STREAM FLOW IN GENERAL TERMS\*

BY MELVIN D. CASLER,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. FRANK S. BAILEY, CECIL E. PEARCE, F. THEODORE  
MAVIS, MORROUGH P. O'BRIEN, R. D. N. SIMHAM, AND MELVIN D. CASLER.

SYNOPSIS

The purpose of this paper is to present a workable general method for the analysis of stream flow in irregular channels—channels in which the invert slope and the channel cross-section are not constant. To attempt to apply the Chezy formula to such a case is to force a perfectly good formula into a situation to which it is not properly applicable. Various scattered attempts have been made to treat this question as applied to special cases, but no satisfactory general treatment has been found in such a form as to be readily followed by most computers.

An exhaustive consideration of the subject of "back-water curves" is contained in "Technical Reports," Part III, of The Miami Conservancy District, but this discussion is confined to "rectangular channels the width of which is uniform and so great in comparison with the depth that the hydraulic radius may be considered equal to the depth."

The discussion contained in this paper is general, and demonstrations of its applicability to weirs, orifices, and siphons are appended.

The Chezy formula,  $v = C \sqrt{r s}$ , is the one most commonly used in stream-flow computations. The factor of longitudinal slope,  $s$ , is sometimes referred to as the slope of the water surface and sometimes as the slope of the bed of the stream. As a matter of fact, it is neither of these except under special conditions. The Chezy slope factor should be defined as the friction factor, or rate of loss of head. This is equal to the slope of the water surface

\* Published in January, 1928, *Proceedings*.

† Mount Vernon, N. Y.

only when the velocity is constant at successive cross-sections and is equal to the slope of the stream bed only when "depth of water plus velocity head" is constant, as demonstrated subsequently.

In the following discussion, the word, "channel", applies to any form of watercourse—canal, conduit, flume, pipe, or stream valley—flowing partly full, or full, or under pressure; and the formulas presented are applicable to all the cases mentioned.

### NOMENCLATURE

The following nomenclature has been used:

Let  $w$  = unit weight of water, in pounds per cubic foot.

$Q$  = quantity of flow, in cubic feet per second.

$W$  = quantity of flow, in pounds per second =  $wQ$ .

$a$  = cross-sectional area of stream, in square feet.

$d$  = maximum depth of water from channel invert to free water surface at the section considered (measured to hydraulic gradient in case of full conduit), in feet.

$b$  = width of channel at water surface (= zero in case of full conduit), in feet.

$p$  = wetted perimeter, in feet.

$r$  = hydraulic radius  $\left( = \frac{a}{p} \right)$ , in feet.

$v$  = mean velocity  $\left( = \frac{Q}{a} \right)$ , in feet per second.

$g$  = gravity factor (= 32.16).

$C$  = Chezy coefficient.

$$m = \frac{1}{2g a^2}$$

$$n = \frac{p}{a^3 C^2}$$

$h$  = effective velocity head  $\left( = \frac{v^2}{2g} = \frac{Q^2}{2ga^2} = mQ^2 \text{ if the velocity is uniform throughout the area, } a \right)$ .

$i$  = invert drop in direction of flow per running foot of channel, in feet. (If invert rises in direction of flow,  $i$  is negative).

$s$  = drop of water surface in direction of flow per running foot of channel, in feet. (If water surface rises in direction of flow,  $s$  is negative).

$f$  = lost head per running foot of channel due to friction between the flowing water and the channel perimeter, in feet. ( $f = nQ^2$ , as demonstrated below, and is always positive).

For general treatment, these quantities are to be regarded as coincident factors at one and the same cross-section of the stream.

Let  $\int_0^l i \, dl$  = total invert drop between two sections  $l$  ft. apart ( $= I$ ) ( $= i l$ , if  $i$  is constant), in feet.

$\int_0^l s \, dl$  = total water-surface drop between two sections  $l$  ft. apart ( $= S$ ) ( $= s l$ , if  $s$  is constant), in feet.

$\int_0^l f \, dl$  = total lost head due to perimeter friction between two sections  $l$  ft. apart ( $= f l$ , if  $f$  is constant), in feet.

$F'$  = total lost head due to internal friction between two sections  $l$  ft. apart (eddies, impact, sudden velocity changes, etc.), in feet.

$F$  = total lost head from all sources between two sections  $l$  ft. apart ( $= F' + \int_0^l f \, dl$ ), in feet.

$F$  and  $F'$  are always positive, while  $I$  and  $S$  are positive if their gradients drop in the direction of flow, but negative if they rise in that direction.

#### EVALUATION OF THE FRICTION FACTOR, $f$

The friction factor,  $f$ , at any particular section may be evaluated as follows:  $f$  is the rate of head loss per foot of channel due to perimeter friction. Hence,  $W f$  equals the energy in foot-pounds lost, or annihilated, as  $W$  moves forward 1 ft.,  $W = w Q = w a v$  and, therefore, the lost energy  $= w a v f$  (Criterion (1)).

This energy loss may be analyzed as follows:  $Q = a v$  and, hence,  $v$  is the length of channel occupied by the quantity of water,  $Q$ , or  $W$ ; and the area of contact between  $W$  and the interior of the channel is  $p v$ .

Experiments have demonstrated that the unit frictional resistance is approximately proportional to the square of the mean velocity; that is, the unit frictional resistance, in pounds per square foot of water contact, acting in a direction opposite to that of the stream flow, is  $K v^2$ ,  $K$  being a constant.

Hence, the total frictional resistance acting against the flow of the quantity of water,  $W$ , is  $(p v) \times (K v^2) = K p v^3$  lb.; and, the energy, in foot-pounds consumed in overcoming this resistance as  $W$  moves forward 1 ft., is  $K p v^3$  (Criterion (2)).

From Criteria (1) and (2):

$$K p v^3 = w a v f, v^2 = \frac{w}{K} \frac{a}{p} f, \text{ and } v = C \sqrt{r f} \dots \dots \dots (1)$$

Equation (1) is the Chezy formula in general terms, in which,  $f$  is the friction factor,  $r = \frac{a}{p}$ , and  $C = \sqrt{\frac{w}{K}}$  = the Chezy coefficient.

$$K = \frac{w}{C^2} = \frac{62.5}{Q^2} \dots \dots \dots (2)$$

It is to be noted that the Chezy formula regards the flow as being governed wholly by the perimeter friction.

From Equation (1),

$$f = \frac{p}{a} \frac{v^2}{C^2} = \frac{p}{a^3 C^2} Q^2 = n Q^2 \dots \dots \dots (3)$$

Since  $h = m Q^2$  and  $f = n Q^2$ , then,

$$f = \frac{n}{m} h \dots \dots \dots (4)$$

$$h = \frac{m}{n} f \left( \frac{m}{n} = \frac{1}{2 g a^2} \frac{a^3 C^2}{p} = \frac{a C^2}{2 p g} = \frac{C^2}{2 g r} \right) \dots \dots \dots (5)$$

#### STEADY NON-UNIFORM FLOW

Fig. 1 represents a general case of "steady flow" in an open channel in which the velocity,  $v$ , is variable and the longitudinal slopes of the water surface and bed of channel are not parallel.  $x x$  and  $y y$  are any two cross-sections  $l$  ft. apart,  $y$  being down stream from  $x$ . The assumption of "steady flow" means that the same quantity of water per second is passing every cross-section of the channel; that is,  $Q_x = Q_y$  and  $W_x = W_y$ .

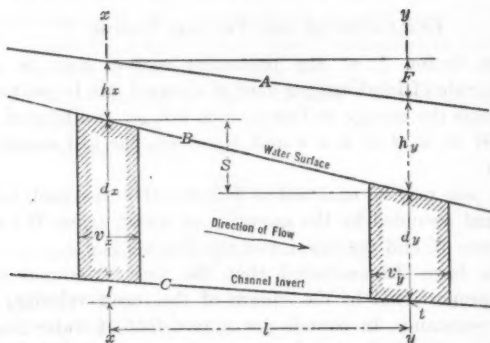

FIG. 1.—LONGITUDINAL SECTION OF FLOWING STREAM.

The quantity of water,  $W$ , occupies the position indicated by the hatched area at Section  $x x$ ; and in flowing from  $x$  to  $y$ , it moves to the position shown by the hatched area at Section  $y y$ . The total energy possessed by this quantity of water,  $W$ , with respect to a common datum through the low point,  $t$ , is less at  $y$  than at  $x$  by the amount of energy lost in friction between  $x$  and  $y$ . Since  $F$  is the total head loss,  $W F$  equals the lost energy.

The static heads with respect to Point  $t$  are  $(d_x + I)$  at  $x$  and  $d_y$  at  $y$ , and hence the potential energies with respect to  $t$  are  $W (d_x + I)$  at  $x$  and

$W d_y$  at  $y$ . The kinetic energy at  $x = \frac{W v_x^2}{2 g} = W h_x$ . The kinetic energy at

$$y = \frac{W v_y^2}{2 g} = W h_y.$$

Hence,

$$W (d_x + I) + W h_x = W d_y + W h_y + W F$$

or,

$$d_x + h_x + I = d_y + h_y + F \dots \dots \dots (6)$$

This relation is shown graphically in Fig. 1, from which it is also apparent that,

$$d_x + I = d_y + S \text{ and } h_x + S = h_y + F \dots \dots \dots (7)$$

The quantity,  $(d + h)$ , is a measure of the energy available at any section and Lines (A), (B), and (C) of Fig. 1 may be designated respectively, "energy gradient", "hydraulic gradient", and "invert gradient". Line (A) always drops in the direction of flow. Lines (B) and (C) usually do the same but, under certain local conditions, either or both of them may rise in the direction of flow.

As a general case, Lines (A), (B), and (C), would not be straight lines. They may, however, be considered as straight for a short elemental length,  $d l$ ; and in that length,  $I = i d l$ ,  $S = s d l$ , and  $F = f d l$  (making the Chezy formula assumption that the perimeter friction is the only source of loss).

Then, from Equations (6) and (7):

$$(d_x + h_x) - (d_y + h_y) = d l (f - i) \dots \dots \dots (8)$$

$$h_x - h_y = d l (f - s) \dots \dots \dots (9)$$

From Equation (1),  $v = C \sqrt{r f}$ . Hence the formula,  $v = C \sqrt{r s}$ , can be true only if  $f = s$ , and from Equation (9), this can be true only if  $h$  (and, hence,  $v$ ) is constant. Likewise, if  $f = i$ , then  $v = C \sqrt{r i}$ , and from Equation (8), it is seen that in this case  $(d + h)$  is constant.

In Equation (6), group the unknown quantities in the left-hand member and the known quantities on the right, as follows:

$$(d_x + h_x) = (d_y + h_y) + (F - I) \dots \dots \dots (10)$$

if proceeding up stream, or

$$(d_y + h_y) = (d_x + h_x) + (I - F) \dots \dots \dots (11)$$

if proceeding down stream.

Equations (10) and (11) are applicable to any invert profile and to any shape of channel section, constant or variable, open or closed, flowing freely or under pressure. The stretches,  $l$ , between Sections  $x$  and  $y$  should be taken sufficiently short to produce the desired degree of accuracy and should terminate at all sudden changes in channel section or invert slope. In case of a sudden head loss, sudden change of section, or a vertical rise or drop in invert elevation, consecutive values of  $(d + h)$  may be computed by taking  $l$  as zero.

From Equations (10) and (11), the energy gradient and the hydraulic gradient (Lines (A) and (B) of Fig. 1) can be computed for any given channel for an assumed  $Q$ .

In proceeding up stream,  $(d_x + h_x)$ , as computed from Equation (10), becomes  $(d_y + h_y)$  for the next up-stream stretch of length,  $l$ ; and in proceeding down stream,  $(d_y + h_y)$ , as computed from Equation (11), becomes  $(d_x + h_x)$  for the next down-stream stretch.

In order to start this procedure, however, a section must be found in which  $d$  and  $h$  are known for the assumed  $Q$ , and the only place where these quantities are independently known in the case of non-uniform flow is at the "critical section" discussed later under that heading.

Equations (10) and (11) cannot be solved directly for the unknown quantities in the left-hand members. In the first place the term,  $F$ , in the right-hand members can be known only approximately until the left-hand members are evaluated. Furthermore, at every section except the "critical section" there will be two possible mathematical values of both  $d$  and  $h$  for any particular value of  $(d + h)$  for a given  $Q$ , one combination of  $d$  and  $h$  giving a small stream section flowing at a high velocity, and the other a larger stream section flowing at a slower velocity.

This may be graphically illustrated as follows: Assume for simplicity a rectangular channel, 10 ft. wide. The coincident values of  $d$  and  $(d + h)$  for flows of 100 and 200 sec.-ft. are computed in Table 1 and plotted in Fig. 2. Assume a  $Q$  of 100 sec.-ft. in this channel and  $(d + h) = 3$ . Then, from Fig. 2, the two possible values of  $d$  are seen to be 0.84 and 2.80.

TABLE 1.— $Q$ -CURVES FOR RECTANGULAR SECTION OF FIG. 2.

$d$ .	$a$ $= 10 d$ .	$m$ $= \frac{1}{2 g a^2}$ .	$Q = 100 \text{ sec.-ft.}$		$Q = 200 \text{ sec.-ft.}$	
			$h$ $= m Q^2$	$d + h$ .	$h$ $= m Q^2$	$d + h$ .
6.0	60	0.0000043	0.04	6.04	0.17	6.17
4.0	40	0.0000097	0.10	4.10	0.39	4.39
3.0	30	0.000173	0.17	3.17	0.69	3.69
2.0	20	0.000689	0.39	2.39	1.55	3.55
1.0	10	0.001555	1.55	2.55	6.22	7.22
0.5	5	0.006219	6.22	6.72	24.88	25.88

The general criterion for selecting the correct value of  $d$  as between these two mathematical possibilities is as follows: The water will flow at such a depth,  $d$ , that the lost head,  $F$ , between any two sections will be as nearly as possible equal to the invert drop,  $I$ , in that same stretch of channel. Referring to Equations (10) and (11), it is seen that this criterion may be expressed as follows: Successive values of  $(d + h)$  will be as nearly as possible equal to each other (Criterion (3)). The application of this criterion is more fully discussed elsewhere in this paper.

The computation of the hydraulic gradient is thus a matter of locating the "critical section" and, with that as a starting point, applying Equation (10) or (11) as guided by Criterion (3).

#### THE CRITICAL SECTION

The "critical section" of a flowing stream is the "neck of the bottle" and controls the flow of the entire stream. The "critical section" is delivering the maximum,  $Q$ , of which it is capable for the particular value of  $(d + h)$  under which it is operating. In other words, the "critical section" is flowing at "maximum efficiency" and is, in general, the only section doing so.

It is apparent from Fig. 2 that for any particular value of  $(d + h)$  in a known section, as  $d$  increases from zero to  $(d + h)$ ,  $h$  decreases from  $(d + h)$  to zero and  $Q$  increases from zero to a certain maximum and again decreases to

zero. For instance, it is seen that in a rectangular section, 10 ft. wide, 200 sec.-ft. is the maximum flow that can be delivered with  $(d + h)$  at a value of 3.48; or, conversely, 3.48 is the minimum value of  $(d + h)$  which will deliver 200 sec.-ft. It is also to be noted that for a  $(d + h)$  of 3.48 the depth of flow,  $d$ , which will deliver the maximum,  $Q$ , is 2.32. Therefore, 2.32 is the "critical depth" for a  $(d + h)$  of 3.48.

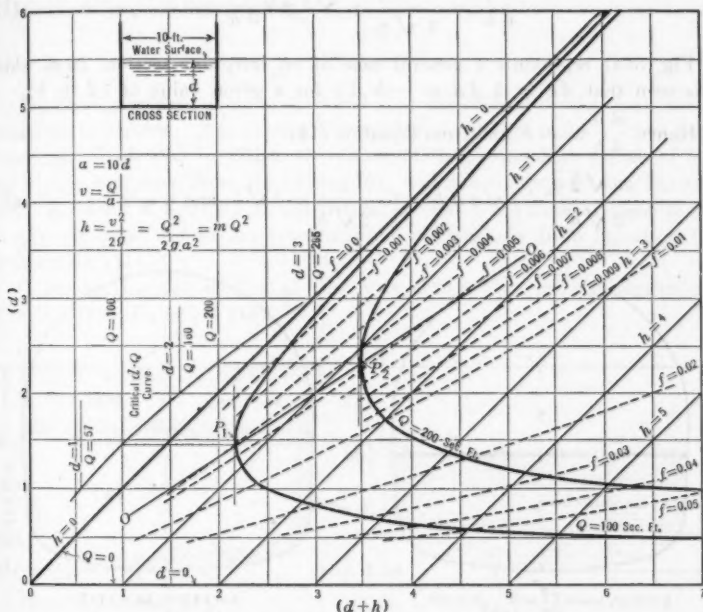

FIG. 2.—ANALYSIS OF RECTANGULAR CHANNEL SECTION.

Hence, for a flow of 200 sec.-ft.  $(d + h) = 3.48$ ,  $d = 2.32$ , and  $h = 1.16$ , if the section is acting as a "critical section". Otherwise,  $(d + h)$  will be greater than 3.48 and  $d$  and  $h$  will each have two possible values as shown by the 200-curve of Fig. 2, the correct values to be determined by Criterion (3).

A direct method for evaluating  $d$  and  $h$ , and likewise  $f$ , at the "critical section" may be derived in general terms by the aid of calculus, as follows: The value of  $h$  to produce a maximum,  $Q$ , for a given  $(d + h)$  is determined

by placing  $\frac{dQ}{dh} = 0$ .

Since  $Q = av$ ,

$$dQ = a(dv) + v(da) \dots \dots \dots (12)$$

Since  $v = \sqrt{2gh}$ ,

$$dv = \frac{\sqrt{2g}}{2\sqrt{h}} dh \dots \dots \dots (13)$$

(assuming uniform velocity throughout the area,  $a$ )

From Equations (12) and (13),

$$dQ = \frac{a\sqrt{2g}}{2\sqrt{h}} dh + \sqrt{2gh} da$$

and for maximum,  $Q$ ,

$$\frac{dQ}{dh} = \frac{a\sqrt{2g}}{2\sqrt{h}} + \sqrt{2gh} \frac{da}{dh} = 0 \dots\dots\dots(14)$$

Fig. 3(a) represents a general case of an irregular section, from which it is seen that  $da = b dd = -b dh$  for a given value of  $(d + h)$ .

Hence,  $\frac{da}{dh} = -b$ , and from Equation (14),

$$\frac{a\sqrt{2g}}{2\sqrt{h}} - b\sqrt{2gh} = 0, \frac{a}{2\sqrt{h}} = b\sqrt{h}, \text{ and } a = 2bh \dots\dots\dots(15)$$

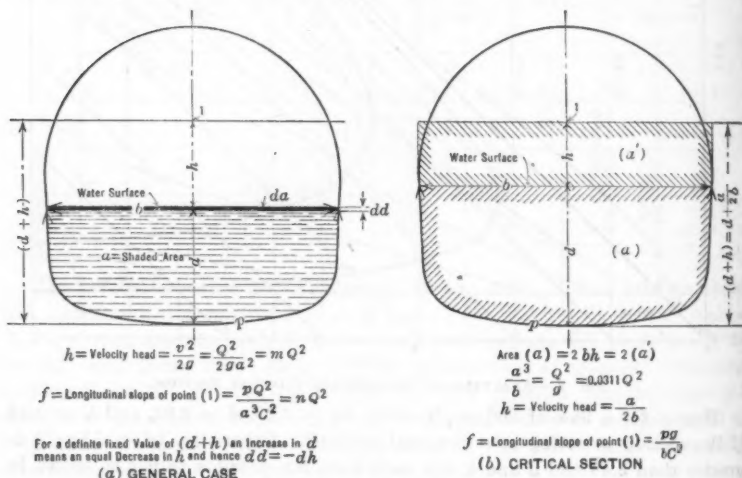

FIG. 3.—CROSS-SECTION OF FLOWING STREAM.

This relation for a maximum,  $Q$ , is shown graphically in Fig. 3(b), in which the area,  $a$ , is double the area,  $a'$ . Hence, at the critical section, from Equation (15):

$$h = \frac{a}{2b} \dots\dots\dots(16)$$

and as  $Q = av = a\sqrt{2gh}$ , at the critical section:

$$Q^2 = a^2 2gh = \frac{a^3 g}{b} \dots\dots\dots(17)$$

$$\frac{a^3}{b} = \frac{Q^2}{g} = 0.0311 Q^2 \dots\dots\dots(18)$$

$$Q = 5.671 \sqrt{\frac{a^3}{b}} \dots \dots \dots (19)$$

Also,

$$f = n Q^2 = \frac{p Q^2}{a^3 C^2} = \frac{p}{a^3 C^2} \frac{a^3 g}{b}.$$

Hence, at the critical section,

$$f = \frac{p g}{b C^2} \dots \dots \dots (20)$$

The three pertinent factors,  $d$ ,  $h$ , and  $f$ , at the critical section may now be computed as follows:  $d$  is obtained by trial or by direct analysis from Equation (18), which also furnishes the corresponding coincident values of  $a$ ,  $b$ , and  $p$ ;  $h$  is computed from Equation (16); and  $f$  is computed from Equation (20). Knowing  $d$ ,  $h$ , and  $f$  at the critical section, the values of these factors at other points of the stream are computed progressively from Equation (10) or Equation (11).

If the rectangular section of Fig. 2 is acting as a critical section and  $Q = 100$ , from Equation (18),

$$\frac{a^3}{b} = 311$$

In this case,

$$\frac{a^3}{b} = b^2 d^3 = 100 d^3$$

hence,

$$d^3 = 3.11$$

and,

$$d = 1.46$$

From Equation (16),

$$h = \frac{a}{2b} = \frac{d}{2} = 0.73$$

$$d + h = 2.19$$

and,

$$p = b + 2d = 10 + 2.92 = 12.92$$

From Equation (20),

$$f = \frac{12.92 \times 32.16}{10 C^2}$$

and, if  $C = 100$ ,  $f = 0.0042$ .

For  $Q = 200$ ,  $d^3 = 12.44$ ;  $d = 2.32$ ;  $h = 1.16$ ;  $d + h = 3.48$ ; and  $p = 14.64$ ; therefore,

$$f = \frac{14.64 \times 32.16}{10 \times 10\,000} = 0.0047$$

The "critical values" of  $d$  and  $(d + h)$  are located at Points  $P_1$  and  $P_2$  of Fig. 2 and, at these points, the  $Q$ -curve tangents must be vertical.

For an irregular section the procedure outlined may become rather complicated. In such a case the critical points, or  $Q$ -curve vertices, may be located as follows for the rectangular section of Fig. 2:

1.—Compute a locus of these vertices as determined by the coincident values of  $(d)$  and  $(d + h)$  of Table 2.

TABLE 2.—CRITICAL FACTORS FOR RECTANGULAR SECTION OF FIG. 2.

$d$ .	$a$ .	$b$ .	$h$ .	$d + h$ .	$Q$ .
			From Equation (16).		From Equation (19).
3	30	10	1.5	4.5	295
2	20	10	1.0	3.0	160
1	10	10	0.5	1.5	57

2.—This locus plots as shown by Line  $OO$  of Fig. 2. For a rectangular section it is a straight line, but for an irregular section the locus, in general, would be curved.

3.—Plot a critical  $d$   $Q$ -curve from the  $(d)$  and  $(Q)$ -columns of Table 2 as indicated at the left of Fig. 2.

4.—The intersection of the proper critical  $(d)$  line with the locus,  $OO$ , will locate the vertex of any desired  $Q$ -curve.

It is also a simple matter to plot a set of  $f$ -curves crossing the  $Q$ -curves of Fig. 2. The  $f$ -curves are computed from Equation (5) as illustrated in Table 3 for the rectangular section of Fig. 2.

TABLE 3.— $f$ -CURVES FOR RECTANGULAR SECTION OF FIG. 2.\*

$d$ .	$a$ .	$p$ .	$m$	$n$	$\frac{m}{n}$ .	$h$ .
			$= \frac{1}{2g a^2}$ .	$= \frac{p}{a^2 C^2}$ .		From Equation (5).
3.0	30	16	0.0000173	0.00000059	293.22	293.22 $f$ .
2.0	20	14	0.0000889	0.000000175	222.29	222.29 $f$ .
1.0	10	12	0.0001555	0.000001200	129.58	129.58 $f$ .
0.5	5	11	0.0006219	0.000008800	70.67	70.67 $f$ .

\*  $C$  is given a constant value of 100.

It is apparent from Table 3 that for any particular value of  $d$ ,  $h$  varies directly as  $f$  and, hence, the  $(d + h)$  increments will vary directly as the  $f$  increments on the same  $d$  line. In other words, equal distances on any horizontal line of Fig. 2 represent equal increments of  $f$ .

Hence, the  $f$ -curves are easily plotted by graduating the horizontal  $d$  lines as follows: For  $d = 3$  in Table 3, if  $f = 0$ ,  $h = 0$ , and  $(d + h) = 3.0$ ; if  $f = 0.01$ ,  $h = 2.93$ ,  $(d + h) = 5.93$ , and that portion of the  $d = 3$  line, between  $(d + h) = 3$  and  $(d + h) = 5.93$ , may be divided into ten equal parts to mark  $f$  values of 0.001, 0.002, 0.003, etc. For  $d = 1$ , if  $f = 0.05$ ,

$h = 6.48$ , and  $(d + h) = 7.48$ ; and by dividing that portion of the  $d = 1$  line, between  $(d + h) = 1$  and  $(d + h) = 7.48$ , into five equal parts, these divisions will be points on the  $f$ -curves, 0.01, 0.02, 0.03, 0.04, 0.05, etc.

The dotted lines of Fig. 2 are plotted in this manner and are seen to check the computed values of  $f = 0.0042$  and  $f = 0.0047$  at Points  $P_1$  and  $P_2$ , respectively.

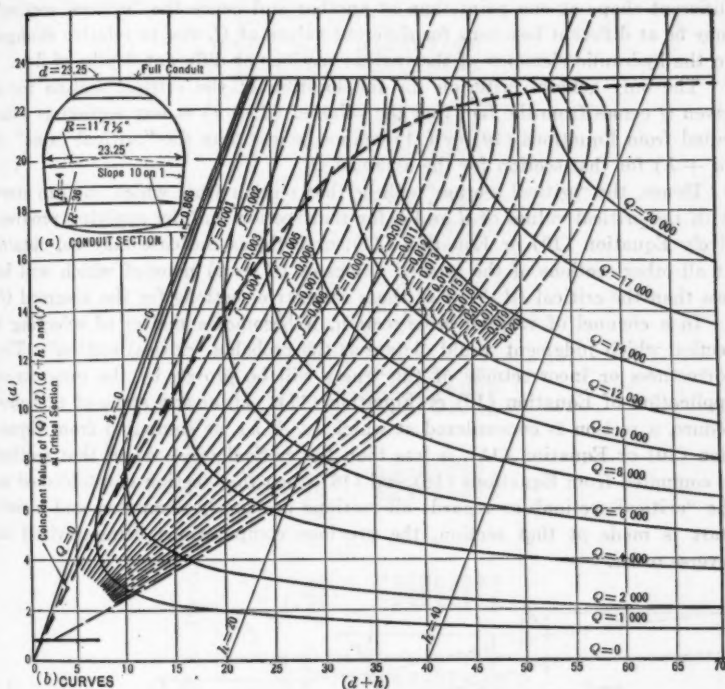

FIG. 4.—ANALYSIS OF CONDUIT.

Fig. 4(b) is a chart embodying the principles of Fig. 2 as applied to the conduit of Fig. 4(a). The preparatory computations for Fig. 4(b) are indicated in Table 4 in which the assumed values of  $C$  are based on the hydraulic radius,  $r$ . The heights from the bottom to the horizontal lines (Fig. 4(a)), are given under  $d$ . The dotted critical factor line of Fig 4(b) becomes horizontal at infinity, and for any finite value of  $h$  the "critical depth" is less than the maximum vertical depth of the conduit. It is also apparent that when the conduit is flowing full or under pressure, a change in  $(d)$  does not alter the area,  $a$ , and, consequently,  $(h)$  and  $(f)$  remain constant for a given  $Q$ , and Fig. 4(b) may be extended to include pressure flows by straight line extensions of the various  $(f)$  and  $(Q)$ -curves above the points where they intersect the  $(d = 23.25)$ -line. All these extensions would be sloped parallel to the  $(h)$ -lines of Fig. 4(b).

The computations indicated in Table 4 are, of course, much simplified for a geometrical channel section in which  $b$ ,  $a$ , and  $p$  can be expressed as simple algebraic functions of the depth,  $d$ .

*Location of Critical Section.*—The first question which comes up in the application of the foregoing principles is, Where is the "critical section" located? As a general proposition, the channel section may possibly have an entirely different shape at one point than at another and hence the "critical section" may be at different locations for different values of  $Q$ , due to relative changes in the hydraulic elements of the various sections at different depths of flow.

The only general criterion for the location of the critical section for a given  $Q$  comes from the fact that the value of  $(d + h)$  at any section as computed from Equations (10) or (11) cannot be less than the "critical value" of  $(d + h)$  for that section for the assumed  $Q$ .

Hence, the "critical section" will be that section from which one can start with the critical values of  $d$  and  $h$  for that section and, by applying progressively Equation (10) or Equation (11), or both, as the case may be, obtain, at all other sections of the stream, values of  $(d + h)$  none of which will be less than the critical  $(d + h)$  of those respective sections for the assumed  $Q$ .

In a channel of varying cross-section, it becomes a matter of selecting a section which judgment would dictate as the probable "critical section". The correctness or incorrectness of this guess will be proven by the progressive application of Equation (10) or Equation (11). If, at any stage of this procedure, a section is encountered at which  $(d + h)$ , as computed from Equation (10) or Equation (11), is less than the critical  $(d + h)$  of that section as computed from Equations (18) and (16), then that section is established as the "critical section" as regards all sections previously computed and a new start is made at that section, the previous computations being revised in reverse order.

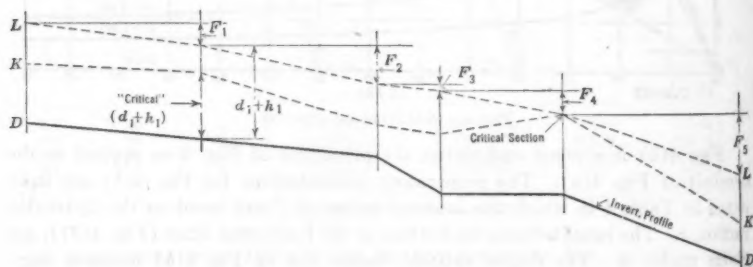

FIG. 5.—CRITICAL SECTION CRITERION.

These principles are graphically represented in Fig. 5, in which, Line  $DD$  is the invert profile; Line  $KK$  is a locus of critical values of  $(d + h)$ ; that is, the vertical intercept between the  $D$ -line and the  $K$ -line at any section is the critical value of  $(d + h)$  at that section for the assumed  $Q$ ; and Line  $LL$  is the "energy gradient" and its successive drops represent the friction losses,  $F$ , in the various stretches of the channel. Hence, Line  $LL$  cannot drop below

\*  $m_1 = 0.0001874$ .  
†  $n_1 = 0.00002395$ .

Line  $KK$  at any point and will be tangent to Line  $KK$  at the "critical section", as indicated in Fig. 5.

The only reason the "critical section" cannot be definitely located by this method is that the  $F$ -drops are not known until the various water depths are evaluated. These principles may be applied as an aid to judgment, however, by computing tentative  $F$ -values and plotting a trial  $L$ -line and shifting it vertically with its datum kept horizontal in order to locate a point of tangency with Line  $KK$  as a first guess on the critical section location.

In many instances, the proposed tentative  $F$ -values might logically be based on the supposition that each and every section is acting as a "critical section". The matter of locating the critical section is, of course, much simplified if the channel cross-section is constant, as in the following example.

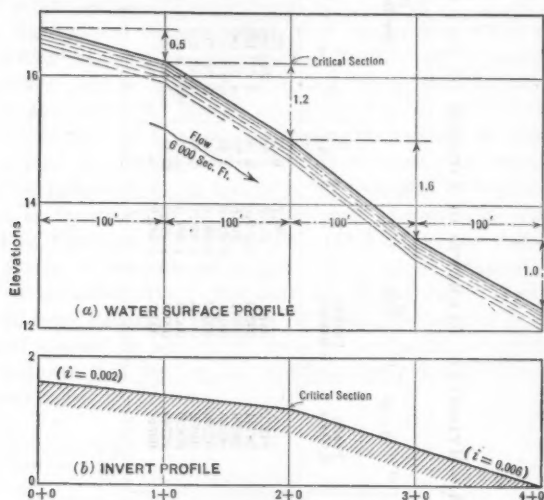

FIG. 6.—ILLUSTRATIVE EXAMPLE.

*Illustrative Example.*—Let Fig. 4(a) represent a conduit of constant cross-section to be analyzed for a flow of 6 000 sec.-ft. (see Fig. 6 and Table 5). Suppose the invert slope,  $i$ , is constant at 0.002 in the up-stream portion of the conduit, changing abruptly to 0.006 at some point between the inlet and the outlet. In a short elemental length,  $dl$ , assume that  $f_x = f_y$  and, considering perimeter friction as the only source of loss, there results from Equation (8),

$$(d_x + h_x) = (d_y + h_y) + dl(f - i)$$

from which it is evident that  $(d + h)$  is increasing down stream if  $i > f$ , and is decreasing down stream if  $i < f$ . Also, if the channel section is constant,  $(d + h)$  will be less at the "critical section" than at any other section of the stream. Hence, in a channel of constant section, if the critical section is located in a stretch where  $i$  is greater than the critical  $f$ , it must be at the

up-stream end of that stretch; and if in a stretch where  $i$  is less than the critical  $f$ , it will be at the down-stream end.

From Fig. 4(b),  $f = 0.0037$  at the critical section in the present example ( $Q = 6000$ ), and, hence, the critical section must be at the up-stream end of the 0.006 slope, or at the down-stream end of the 0.002 slope. Since these two points coincide, the critical section is definitely located. If the slopes had been reversed, however, with 0.006 at the up-stream end and 0.002 at the down-stream end, there would have been two possible locations of the critical section to investigate, one at the inlet and one at the outlet, with perhaps the possibility of a critical section at each end and a hydraulic jump within the conduit to bridge the change from low stage to high stage.

TABLE 5.—ANALYSIS OF CONDUIT WITH CONSTANT CROSS-SECTION.\*

Station.	$d + h$ .	$d$ .	$h$ .	$f$ .	$F$ .	$I$ .	$S$ .	Invert elevation.	Water surface elevation.

4 + 0	20.57	12.4	8.17	0.0049	0.47	0.6	1.0	0	12.4

\* See Fig. 6.

The hydraulic gradient may now be computed by starting at the critical section which, in this case, is between the inlet and the outlet, and proceeding from there both up stream and down stream. Hence, start at the vertex of the  $Q = 6000$ -curve and apply Equation (10) to go up stream, or Equation (11) to go down stream.

Let  $I = i l$  and assume  $F = \left( \frac{f_x + f_y}{2} \right) l$ , taking  $l$  in 100-ft. stretches. To satisfy Criterion (3),  $F$  must be as nearly as possible equal to  $I$  or, in the present case,  $\frac{1}{2} (f_x + f_y)$  must be, as nearly as possible, equal to  $i$ .

In proceeding up stream from the critical section,  $f_y = 0.0037$  and  $i = 0.002$ , and it is apparent that one must follow the  $Q$ -curve upward from the dotted line of Fig. 4(b) to make  $\frac{1}{2} (f_x + f_y)$  approach the value of  $i$ .

Hence, there is the following general criterion in the application of Fig. 4(b), or a similar chart for any constant-section channel, providing  $f$  is the only source of head loss: Follow the  $Q$ -curve upward or downward from its vertex accordingly as  $f$  at the vertex is, respectively, greater or less than  $i$  (Criterion (4)).

In this example there is, at the critical section, at the break in invert gradients,  $d = 13.8$ ,  $(d + h) = 20.25$ , and  $f = 0.0037$ , as read from the vertex of the  $Q = 6000$ -curve of Fig. 4(b).

Proceeding up stream and following the  $Q$ -curve upward from its vertex, per Criterion (4), it is found that, at a point 100 ft. up stream,  $(d + h) = 20.39$  and  $f = 0.0031$ , to satisfy Equation (10) in the following form:

$$(d_x + h_x) - \frac{l}{2} f_x = (d_y + h_y) + \frac{l}{2} f_y - l i \dots \dots \dots (21)$$

$$\left( \text{since } F = \left( \frac{f_x + f_y}{2} \right) l \text{ and } I = i l \right).$$

From Equation (21),

$$(d_x + h_x) - 50 f_x = 20.25 + 0.185 - 0.2 = 20.235$$

and,

$$20.39 - (50 \times 0.0031) = 20.235$$

The corresponding water depth,  $d$ , as given by Fig. 4(b), is 14.8.

At the up-stream end of the next 100-ft. stretch  $(d + h) = 20.49$  and  $f = 0.0029$  as follows:

$$(d_x + h_x) - 50 f_x = 20.39 + (50 \times 0.0031) - 0.2 = 20.345$$

$$20.49 - (50 \times 0.0029) = 20.345$$

$$d = 15.1$$

and so on to the inlet.

Proceeding down stream from the critical section,  $i = 0.006$  and, therefore, it must follow the  $Q$ -curve downward from its vertex. At a point 100 ft. down stream from the critical section,  $(d + h) = 20.44$  and  $f = 0.0045$  from the following adaptation of Equation (11):

$$(d_y + h_y) + \frac{l}{2} f_y = (d_x + h_x) - \frac{l}{2} f_x + l i \dots \dots \dots (22)$$

$$(d_y + h_y) + 50 f_y = 20.25 - 0.185 + 0.6 = 20.665$$

$$20.44 + (50 \times 0.0045) = 20.665$$

$$d = 12.8$$

At the down-stream end of the next 100-ft. stretch,  $(d + h) = 20.57$  and  $f = 0.0049$  as follows:

$$(d_y + h_y) + 50 f_y = 20.44 - (50 \times 0.0045) + 0.6 = 20.815$$

$$20.57 + (50 \times 0.0049) = 20.815$$

$$d = 12.4$$

and so on to the outlet.

These results are given in Table 5 and plotted in Fig. 6. In this example,  $d$  was computed at points a definite distance apart. This is the method that would be used in the precise analysis of a channel of changing cross-section, plotting curves similar to those of Fig. 4(b) for each section considered.

In a channel of constant cross-section this process can be simplified somewhat by assuming definite values of  $d$  and then computing where these depths would occur by solving directly for  $l$  instead of assuming  $l$  and solving for  $d$  by trial and error.

For instance, starting with  $d = 13.8$  ( $d + h$ ) = 20.25, and  $f = 0.0037$  at the critical section, it is possible to determine directly where  $d = 14.8$  as

follows: If  $d_x = 14.8$ , then from Fig. 4(b),  $(d_x + h_x) = 20.39$  and  $f_x = 0.0031$ . Then from Equation (21),

$$l \left( \frac{f_x}{2} + \frac{f_y}{2} - i \right) = (d_x + h_x) - (d_y + h_y)$$

$$l (0.00155 + 0.00185 - 0.002) = 20.39 - 20.25$$

$$l = \frac{0.14}{0.0014} = 100$$

If the water level is known at one or more points of the channel, the discharge will be a value of  $Q$  which will satisfy the known conditions without resulting in a value of  $(d + h)$  at any section less than its critical  $(d + h)$  for that  $Q$ .

In such a case a situation might be found in which no section of the channel would be operating as a "critical section". If the velocity of approach above the conduit inlet and the velocity of the tail-water below its outlet are so small that they may be neglected, then  $h$  at those points becomes zero and Equation (10) becomes,

$$d_x = d_y + F - I, \text{ or } F = d_x - d_y + I$$

in which,  $d_x$  and  $d_y$  are in the still water of the approach pool and tail-water pool, respectively;  $I$  is the total invert drop between those points; and  $F$  is the total head loss from all sources.

In this case the discharge would be the maximum value of  $Q$  which could be delivered with a total loss of head equal to this value of  $F$ , unless the resulting  $(d + h)$  at some section should be below its critical value, in which case the discharge would be governed by the "critical section". The analysis, of course, must include the  $F$  losses at inlet and outlet or elsewhere due to sudden velocity changes.

If the channel in the foregoing example had not been of constant cross-section it would have been necessary to prepare a chart similar to Fig. 4(b) for each of the different channel sections, applying each one in its proper place and observing the general criterion in the location of the "critical section". A sudden change of section would introduce a sudden head loss and a corresponding sudden drop in the value of  $(d + h)$ .

#### WEIRS, DAMS, AND FALLS

The conditions at the crest of a weir, dam, or falls are usually those of a critical section; that is, the stream section on the crest is delivering the maximum  $Q$  possible for the particular value of  $(d + h)$  under which it is operating, without hindrance or limitation from other sections up stream or down stream.

Assuming the stream section on the crest to be rectangular,  $a = bd$  and the following simplifications of the general critical section Equations (16) and (19) occur, representing conditions at the weir crest.

From Equation (16),

$$h = \frac{d}{2} \dots \dots \dots (23)$$

and,

$$d + h = 3 h = \frac{3}{2} d \dots \dots \dots (24)$$

From Equation (19),

$$Q = 5.671 b d^{\frac{3}{2}} \dots \dots \dots (25)$$

and,

$$d = 0.3145 \left( \frac{Q}{b} \right)^{\frac{2}{3}} \dots \dots \dots (26)$$

Equation (25) should give the discharge over any form of rectangular weir, dam, or falls,  $b$  and  $d$  being the exact dimensions of the stream of water on the weir crest.

Because of difficulties in the way of measuring  $d$  at the crest, weir discharge is usually expressed in terms of the static head a "short distance up stream" from the weir. This head, usually designated as  $H$ , is the difference in elevation between the weir crest and the water surface at the section where  $H$  is measured, which corresponds to Section  $x$  of Fig 1, and the weir crest corresponds to Section  $y$ .

Neglecting friction between  $x$  and  $y$ , Equation (10), as shown in Fig. 7, becomes,

$$d_x + h_x + I = d_y + h_y \dots \dots \dots (27)$$

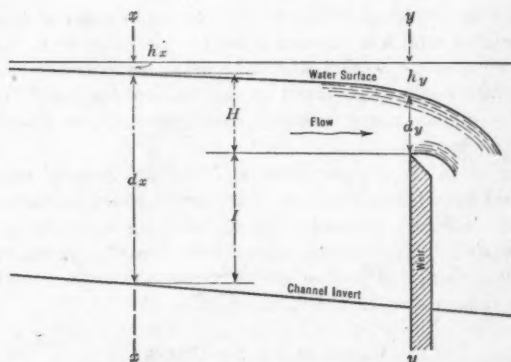

FIG. 7.—LONGITUDINAL SECTION OF FLOWING STREAM ABOVE A WEIR.

In Fig. 7,  $I$  is negative since the invert is higher at  $y$  than at  $x$ . Also,  $d_x + I = H$  and from Equation (24),  $d_y + h_y = \frac{3}{2} d_y$ . Hence, from Equation (27),

$$\frac{3}{2} d_y = H + h_x$$

and,

$$d_y = \frac{2}{3} (H + h_x) \dots \dots \dots (28)$$

and from Equations (25) and (28),

$$Q = 3.087 \, b \, (H + h_x)^{\frac{3}{2}} \dots \dots \dots (29)$$

In Equation (29),  $h_x$  is the effective velocity head at Section  $x$ , where  $H$  is measured, and  $b$  is the net width of the stream at the weir crest.

In the Francis weir formula,

$$Q = K \, b \, H^{\frac{3}{2}} \dots \dots \dots (30)$$

in which,  $K$  is a constant.

From Equations (25) and (30),

$$K \, H^{\frac{3}{2}} = 5.671 \, d_y^{\frac{3}{2}}$$

and,

$$K = 5.671 \left( \frac{d_y}{H} \right)^{\frac{3}{2}} \dots \dots \dots (31)$$

It should be kept in mind that these equations assume a uniform velocity throughout the entire area of every cross-section of the stream. ( $v$  = the mean velocity,  $\frac{Q}{a}$ , and  $h = \frac{v^2}{2g}$ .)

If the velocity in any cross-section is not uniform, then  $h > \frac{v^2}{2g}$ . Equation (25) is theoretically correct on the assumption that the velocity on the crest is uniform throughout the area,  $b$ ,  $d$ ,  $b$  and  $d$  being the exact dimensions of the stream on the crest.

Equation (29) is theoretically correct on the further assumption of uniform velocity at Section  $x$  and no friction losses between  $x$  and  $y$ .

In Equation (30), if  $K$  is determined experimentally it includes the effect of friction losses and non-uniform velocities, but the evaluation of  $K$  from Equation (31) as plotted in Fig. 8, involves the same assumptions as Equation (29).

It is not usually feasible to measure  $d_y$  with any degree of accuracy, but the principles of Equation (31) may be analyzed in the following manner:

$$b_y \, d_y = a_y \quad \text{and} \quad a_y \, v_y = a_x \, v_x$$

from which,

$$b_y \, d_y \, \sqrt{h_y} = a_x \, \sqrt{h_x}$$

or,

$$b_y^2 \, d_y^2 \, h_y = a_x^2 \, h_x \dots \dots \dots (32)$$

From Equation (23),  $h_y = \frac{1}{2} \, d_y$ , and, from Equation (28),  $h_x = \frac{3}{2} \, d_y - H$ .

Hence, from Equation (32),

$$\frac{1}{2} \, b_y^2 \, d_y^3 = a_x^2 \left( \frac{3}{2} \, d_y - H \right)$$

or,

$$\left( \frac{a_x}{b_y} \right)^2 = \frac{d_y^3}{3 \, d_y - 2 \, H} \dots \dots \dots (33)$$

5.671 =  $\sqrt{g}$  and, hence, from Equation (31),  $d_y = \frac{H K^{\frac{2}{3}}}{g^{\frac{1}{3}}}$ . Substituting this value of  $d_y$  in Equation (33),

$$\frac{a_x}{b_y} = k H \dots \dots \dots (34)$$

in which,

$$k = \frac{K}{g^{\frac{1}{3}} \sqrt{3 K^{\frac{2}{3}} - 2 g^{\frac{1}{3}}}} \dots \dots \dots (35)$$

Coincident values of  $K$  and  $k$  from Equation (35) and corresponding values of  $\frac{a_x}{b_y}$  for various values of  $H$  are listed in Table 6 and plotted in Fig. 8.

\* See Fig. 8.

$$\dagger 3.087 = \sqrt{g} \left( \frac{2}{3} \right)^{\frac{3}{2}}.$$

$$\dagger 5.671 = \sqrt{g}.$$

The  $K$  lines of Fig. 8 would be straight if plotted to natural scales, but logarithmic plotting is used to reduce the size of the diagram. It is apparent from Fig. 7 that  $H$  may have any value between the limits,  $d_y$  and  $(d_y + h_y)$ , depending on the location of Section  $x$ .

From Equation (31), when  $H = d_y$ ,  $K = 5.671$ ; and when  $H = d_y + h_y$ ,  $\left( = \frac{3}{2} d_y \right)$ ,  $K = 5.671 \left( \frac{2}{3} \right)^{\frac{3}{2}} = 3.087$ . Hence,  $K$  must lie between the two limits, 5.671 and 3.087.

From Equations (35) and (34), for  $K = 5.671 (= g^{\frac{1}{2}})$ ,  $\frac{a_x}{b_y} = H$ ; and for  $K = 3.087 \left( = g^{\frac{1}{2}} \times \left( \frac{2}{3} \right)^{\frac{3}{2}} \right)$ ,  $\frac{a_x}{b_y} = \infty$  for all values of  $H$ . That is,  $a_x = \infty$ , or, in other words,  $h_x = 0$ .

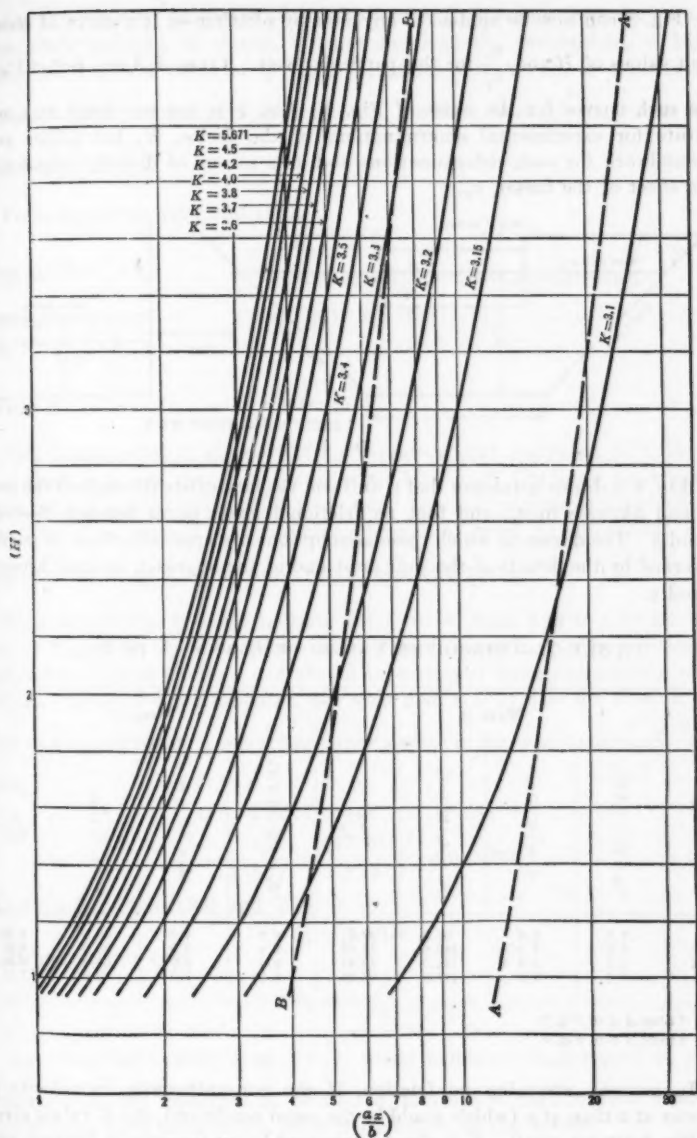

FIG. 8.—VALUES OF  $K$  IN  $Q = KbH^{3/2}$ , ASSUMING UNIFORM VELOCITIES AND NO FRICTION.

Fig. 8 can now be applied to any weir by plotting on it a curve of coincident values of  $H$  and  $\frac{a_x}{b_y}$  for that particular weir. Lines  $AA$  and  $BB$  of Fig. 8 are such curves for the weirs of Fig. 9. Fig. 8 is not put forth as a substitute for experimental determinations of the factor,  $K$ , but rather as a groundwork for such determinations and as a means of directly introducing the effect of the factor,  $a_x$ .

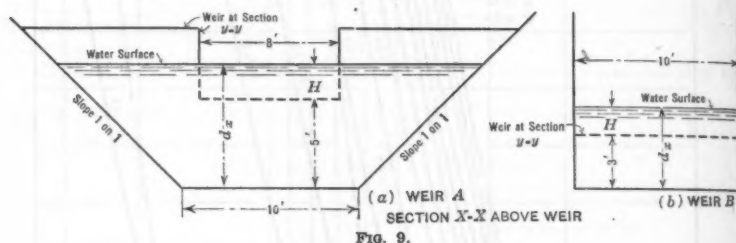

Fig. 8 is drawn assuming that a uniform velocity exists throughout the area,  $a_x$  and likewise in  $a_y$ , and that no frictional losses occur between Sections  $x$  and  $y$ . The degree to which these assumptions are approached are, of course, governed by the details of the weir crest and of the approach channel between  $x$  and  $y$ .

\* Line  $AA$  of Fig. 8.

† Line  $BB$  of Fig. 8.

In general, assuming no friction, if the non-uniformity in velocity is greater at  $x$  than at  $y$  (which would be the usual condition), the  $K$  values given by Fig. 8 are too small.  $K$  is always decreased by an increase in friction, and *vice versa*. This Fig. 8 gives a definite value of  $K$  for any value of  $H$  as measured on any particular weir, on the assumption of uniform velocity distributions and no friction.

Any experimental determination of the factor,  $K$ , differing from the values given would indicate, of course, a departure from the assumptions of Fig. 8 and would give a value of  $Q$  from Equation (30), which, if substituted in Equation (29), would give a value of  $h_x$  differing from  $\frac{v_x^2}{2g}$  ( $v_x$  being the mean velocity,  $\frac{Q}{a_x}$ ).

From Equations (29) and (30),

$$h_x = k' H \dots \dots \dots (36)$$

in which,

$$k' = 0.4717 K^{\frac{2}{3}} - 1 \dots \dots \dots (37)$$

also,

$$0.4717 = \frac{3}{2 g^{\frac{1}{3}}}$$

Coincident values of  $K$  and  $k'$  from Equation (37) are listed in Table 6, from which it is seen that  $k' = 0$  only when  $K = 3.087$  (its lower limit), and hence for any greater value of  $K$  there must be some velocity of approach in some part of  $a_x$  even if  $a_x$  is infinitely large.  $h_x$  from Equation (36) will equal  $\frac{v_x^2}{2g}$  only when  $K$  in Equation (37) agrees with Fig. 8.

Line  $BB$  of Fig. 8 would indicate values of  $K$  from 3.13 to 3.34 for the weir of Fig. 9(b), as  $H$  increases from 1 to 4, assuming uniform velocity distribution and no friction, and should be correct if these assumptions were realized. Suppose experiments on this weir give a  $K$  of 3.33 for  $H = 1$ , instead of 3.13, indicating a correction factor applied to Fig. 8 of 1.064 ( $= \frac{3.33}{3.13}$ ).

Then,

$$Q = 3.33 \times 9.8 \times 1 = 32.634$$

$$\frac{v_x^2}{2g} = \frac{Q^2}{2g a_x^2} = \frac{(32.634)^2}{2g (40)^2} = 0.01035$$

and, from Equations (36) and (37),

$$h_x = 0.0518$$

Hence, in this case,

$$h_x = 5 \frac{v_x^2}{2g}$$

An "effective" velocity head of  $5 \frac{v_x^2}{2g}$  would indicate a high degree of non-uniformity in the velocities at Section  $x$ , probably a high surface velocity with perhaps some dead water, or even back-flow, at the invert.

Let  $H_0$  equal the value of  $H$  at a point where there is no velocity of approach. Then,  $h_x = 0$ , and, from Equation (29),

$$Q = 3.087 b H_0^{\frac{3}{2}} \dots \dots \dots (38)$$

from which,

$$H_0 = 0.4717 \left( \frac{Q}{b} \right)^{\frac{2}{3}} \dots \dots \dots (39)$$

which is the elevation of the reservoir flow line above the crest of a spillway weir, assuming uniform velocity on the crest and no friction losses in approaching the weir. ( $Q$  = flow over weir and  $b$  = net width of stream on crest.)

#### ORIFICES

Since Equation (10) is perfectly general, it would be possible to apply its principles to an orifice. Sections  $x$  and  $y$  are regarded as being, respectively, above and below the plane of the orifice. At the plane of the orifice, there is an intermediate section, 0-0. Uniform velocity distributions are assumed at all sections.

$$Q = a_x v_x = a_0 v_0 = a_y v_y \dots \dots \dots (40)$$

Let the head loss between Sections  $x$  and  $y$ , equal,

$$F = k h_0 \dots \dots \dots (41)$$

in which,  $k$  is a coefficient, depending on local conditions.

$$h_0 = \frac{v_0^2}{2g} = \frac{Q^2}{2g a_0^2}, \quad h_x = \frac{Q^2}{2g a_x^2}, \quad \text{and} \quad h_y = \frac{Q^2}{2g a_y^2} \dots \dots \dots (42)$$

From Equation (10),

$$(d_x + h_x) = (d_y + h_y) + (k h_0 - I) \dots \dots \dots (43)$$

$S$  is the water-surface difference between  $x$  and  $y$ , and  $S = d_x + I - d_y$ . Hence, from Equation (43),

$$S = k h_0 + h_y - h_x \dots \dots \dots (44)$$

From Equations (44) and (42),

$$2gS = Q^2 \left( \frac{k}{a_0^2} + \frac{1}{a_y^2} - \frac{1}{a_x^2} \right)$$

and,

$$Q = a_x a_0 a_y \sqrt{\frac{2gS}{k \frac{a_x^2}{a_y^2} + a_0^2 \frac{a_x^2}{a_y^2} - a_0^2 \frac{a_x^2}{a_y^2}}} \dots \dots \dots (45)$$

Compare Equation (45) with the following formula:

$$Q = c a_0 \sqrt{2gS} \dots \dots \dots (46)$$

in which,  $c$  is a "coefficient of discharge" in terms of  $S$ .

From Equations (45) and (46),

$$k = \left( \frac{1}{c} \right)^2 - \left( \frac{a_0}{a_y} \right)^2 + \left( \frac{a_0}{a_x} \right)^2 \dots \dots \dots (47)$$

$a_y = c_1 a_0$ , in which,  $c_1$  is the coefficient of contraction, and, hence,

$$k = \frac{1}{c^2} - \frac{1}{c_1^2} + \left( \frac{a_0}{a_x} \right)^2 \dots \dots \dots (48)$$

Equations (47) and (48) lead to the following special formulas:

If  $a_x = a_y$ ,

$$k = \frac{1}{c^2} \dots \dots \dots (49)$$

If the velocity of approach is zero,  $a_x = \infty$ , and,

$$k = \frac{1}{c^2} - \frac{1}{c_1^2} \dots \dots \dots (50)$$

If  $c_1$  in Equation (50) is 1.0,

$$k = \frac{1}{c^2} - 1 \dots \dots \dots (51)$$

If  $c_1$  in Equation (50) is 0.6,

$$k = \frac{1}{c^2} - 2.78 \dots \dots \dots (52)$$

TABLE 8.—COINCIDENT VALUES OF  $c$  AND  $k$ .

Value of $c$ .	Values of $k$ .		
	From Equation (49).	From Equation (51).	From Equation (52).
0.5	4.0	3.0	1.22
0.6	2.78	1.78	0
0.8	1.56	0.56	....
1.0	1.0	0	....

It is to be remembered that  $c$  and  $k$  in Table 8 are coefficients, such that,  $Q = c a_0 \sqrt{2gS}$  (Equation (46)) and  $F = k h_0$  (Equation (41)).

Since  $F$  cannot be negative,  $k$  cannot be negative and, hence, from Equation (50), it follows that, in the case of zero velocity of approach,  $c$  cannot be greater than  $c_1$ .

From Equations (42) and (46),

$$h_0 = c^2 S \dots \dots \dots (53)$$

and, hence, from Equation (41),

$$F = k c^2 S \dots \dots \dots (54)$$

and,

$$k c^2 = \frac{F}{S} \dots \dots \dots (55)$$

It may be that this discussion of orifices is more academic than useful, but it brings out some interesting relations and demonstrates the general applicability of the basic equations.

### SIPHONS

In the basic equations, (6), (10), and (11),  $d$  is the vertical distance from the invert to the "hydraulic gradient". The "hydraulic gradient" (Line  $B$ , Fig. 1) is the water surface profile on the assumption of equal barometric pressures on the water surfaces at all sections.

Let  $D$  = the water head corresponding to the barometric pressure; and  $d'$ , the vertical distance from the invert to the water surface. Then the basic energy equation, Equation (6), may also be expressed as:

$$d'_x + D_x + h_x + I = d'_y + D_y + h_y + F \dots \dots \dots (56)$$

If  $D$  is constant, the water surface profile and the "hydraulic gradient" coincide, and  $d$  and  $d'$  are synonymous at all sections.

Subtracting Equation (6) from Equation (56),

$$d'_x + D_x - d_x = d'_y + D_y - d_y \dots \dots \dots (57)$$

Suppose the water surface coincides with the hydraulic gradient at Section  $x$ . Then,  $d_x = d'_x$  and from Equation (57),

$$d'_y = d_y + (D_x - D_y) \dots \dots \dots (58)$$

On the further supposition that  $D_y = 0$

$$d'_y = d_y + D_x \dots \dots \dots (59)$$

Equation (59) represents the conditions existing when Section  $x$  is in an open channel or pool and Section  $y$  is in a closed pipe running full. In this case,  $D_x$  is the atmospheric head and  $d'_y$  is the vertical distance from the invert to the water level in a vertical vacuum tube at Section  $y$  and is the maximum possible water depth at that section.

The theoretical value of  $D_x$  is about 34 ft., but as a matter of practice it is seldom safe to assume  $D_x$  as greater than 28 ft.

In computing a full conduit or siphon down stream from open head-water, the first application of Equation (56) would be as follows:

$$(d'_y + h_y) = (d'_x + D_x + h_x) + (I - F) \dots \dots \dots (60)$$

In the next succeeding stretch of conduit, Section  $y$  becomes Section  $x$ ,  $D_x$  becomes zero, and,

$$(d'_y + h_y) = (d'_x + h_x) + (I - F) \dots \dots \dots (61)$$

Since  $h$  and  $F$  are independent of  $d$  in a full conduit, Equation (61) will produce the same results as Equation (11) unless  $d$ , at some section, becomes less than the vertical depth of the conduit at that point. In that case the conduit, instead of flowing at the depth,  $d$ , will continue to flow full unless  $d'$  ( $= d + \text{atmospheric head}$ ) becomes less than the full conduit depth.

## DISCUSSION

FRANK S. BAILEY,\* Assoc. M. Am. Soc. C. E. (by letter).—The author seems to have accomplished his purpose, as stated in his Synopsis, "to present a workable general method for the analysis of stream flow in irregular channels". His fundamental assumptions are generally accepted as fair ones; his development of the equations showing the relations between the various factors governing the flow are logical; and, in so far as the writer has discovered, his mathematics are correct. Diagrams showing the relations of  $d$  plus  $h$ , and  $Q$  have been used for several years,† but the addition of  $f$ -curves by the author is a valuable new development.

Of the numerous papers and articles which have been published in the past with the object of determining the location of the water surface for a given rate of flow in an irregular channel, few, if any, are so comprehensive and clearly stated as that of Mr. Casler. His definition of the Chezy slope factor is commendable.

The fact that a given quantity of water can flow at different depths in a channel; may result in considerable damage if care is not exercised in the design of the channel. Suppose that a spillway channel for an earth dam is located on the side of a hill which rises from the bed of the stream, and that it is necessary to build a wall on the lower side of the channel, of sufficient height to prevent any flood flow from overtopping the wall with possible injury to the down-stream slope of the dam. A spillway channel wall might be designed on the basis that in all cases the water would flow at high velocity at a low depth and if, due to some unexpected cause, the actual velocity were lower and the depth higher than anticipated, the wall itself might act as a spillway, with undesirable consequences.

Karl R. Kennison, M. Am. Soc. C. E., mentions‡ the case of two high flood flows of not greatly different amounts which ran at different depths in a wooden flume, and in his discussion of that paper, the late Frederic P. Stearns, Past-President, Am. Soc. C. E., described§ at greater detail the same phenomenon. If a horizontal deflection or a curve exists in the channel, the chances of a mistake in the design are increased, and more knowledge on the subject of loss of head in curves and on differences in elevation of water on the inner and outer edges of curves would be helpful.

An entering or discharging stream of water at the intersection with a branch channel may also have to be taken into account. Losses due to intersecting streams have been ably treated|| by J. C. Stevens, M. Am. Soc. C. E., from a theoretical standpoint.

\* Structural Designer, New England Power Constr. Co., Boston, Mass.

§ *Loc. cit.*, p. 368.

|| "Theoretical Energy Losses in Intersecting Pipes," *Engineering News-Record*, July 22, 1926, p. 140.

The author's treatment of (a) flow over weirs; (b) the effects of height of weir above the bottom of the channel; (c) area of channel above the weir as affecting the velocity of approach; and (d) flow over the weir, is novel and ingenious.

CECIL E. PEARCE,\* ASSOC. M. AM. SOC. C. E. (by letter).—This excellent paper should be welcomed by all hydraulic designers. Basically, nothing new is presented, but the treatment is exceptionally clear, and presents the facts in a readily usable form. Having set up the fundamental energy equation, which is well known and is commonly called "Bernoulli's theorem", the author bases the larger part of his mathematics upon it, of necessity. The treatment of the critical section, however, and the curves used, form valuable tools which lead to a clearer understanding and shorten the work involved in computing the water surface in an irregular channel or conduit for a given discharge.

The writer, in calculating the flood discharges through the Exchequer Dam and Power House, in 1926, used a step-by-step process, with Chezy's formula,  $c = C \sqrt{rs}$ , obtaining the proper elements by trial and error. The determination of the proper trial was based on the same fundamental reasoning as that of the author.

The conduit was very irregularly shaped. The steps were as follows:

- 1.—Assume a given value of  $Q$ , say, 300 sec-ft.
- 2.—For a first trial, assume that, with 300 sec-ft. flowing, the water will have a certain depth at the lower end. Since  $Q = av$ , the corresponding velocity at that lower end may be computed.
- 3.—With this as a basis, calculate by trial and error what the water surface elevation would be at every point along the irregular conduit, and, finally, in the reservoir.
- 4.—Repeat this process a number of times for  $Q = 300$  by starting with different assumed depths of water at the lower end.

A number of such computations gives an equal number of possibilities for the water-surface profile. Any assumed elevation of the water surface at the lower end determines the water elevation in the reservoir. Which of these profiles is the proper one?

To answer this question, consider what holds the water surface where it is. If a glass of water is emptied on a flat surface, it immediately tries to flatten out to zero thickness. The same is true of the water in a channel; all that holds the water surface where it is is the back pressure. The water, in attempting to flatten out, meets with obstacles (resistance). Considering that the only resistance causing a reaction to the flow of the water is the frictional force and the resistance of inertia in producing velocity, it is those two forces that supply the back pressure to restrain the water surface.

Also, with any given surface elevation in a reservoir, there must be one maximum value of  $Q$  which can be discharged through a given channel. Referring to Fig. 10,  $F$  represents energy consumed in overcoming friction;

\* Chf. Designing Engr., Pasadena Water Dept., Pasadena, Calif.

and  $h_f$  represents the energy consumed in producing velocity. Therefore,  $(h_f + F)$  is the total energy consumed in overcoming friction and producing velocity.

By the theory of least work, however, the total energy consumed must be a minimum. Therefore,  $(h_f + F)$  must be a minimum, and, since Points (A) and (D) are given, Point (C) must rise as high as possible. For a higher portion of Point (C) the value of  $Q$  would be less, or the elevation at Point (E) would increase.

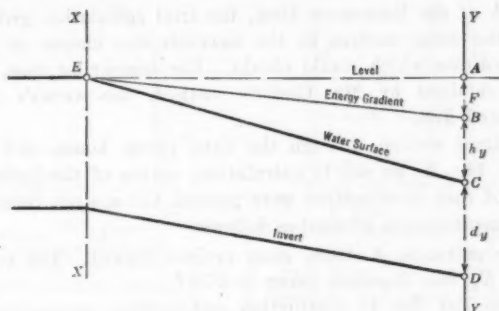

FIG. 10.

Hence, for a given maximum discharge,  $Q$ , and a given water surface elevation at Point (E), the water surface,  $E-C$ , will be as nearly level as possible, or for a given  $Q$  and the water surface as nearly level as possible (in order to comply with the minimum energy loss requirement), the water surface elevation at Point (E) will be the minimum which would discharge the given  $Q$ . This is necessary in order to make  $Q$  the maximum for that elevation.

If it is hard to visualize the theory entirely, a simple calculation will make the statement clearer:

- (1) Consider a short channel leading from a reservoir.
- (2) Assume a given discharge,  $Q$ .
- (3) By successively taking assumed depths at the lower end, calculate what the water surface elevation in the reservoir will be in order to give that discharge.
- (4) Suppose at first shallow depths are assumed at the lower end; then, in successive trials, somewhat greater and greater depths at the lower end are taken.
- (5) For the first trial the very shallow depth requires a great velocity; consequently, the friction loss and velocity head loss are great, and a relatively high water elevation in the reservoir is required to furnish the necessary heads.
- (6) For the next trial, with a greater depth at the lower end, the velocity is less, and consequently the friction loss is less. The elevation of the water surface in the reservoir then need not be as great as in the first trial. Finally, after repeated trials the reservoir elevation reaches a minimum, and then begins to rise

again. Or it may be found that, with the minimum head in the reservoir, the total energy loss is a minimum in order to discharge the given  $Q$ , and that with another trial calculation, assuming the water surface at the lower end of the conduit to be a little higher than for the minimum reservoir elevation, either the water surface in the reservoir must rise to create the given  $Q$ , or the discharge,  $Q$ , will decrease. This shows, as before, that this minimum elevation in the reservoir represents the water surface profile of minimum energy loss for the specific task of discharging the given maximum  $Q$ .

In the case of the Exchequer Dam, the trial calculation giving the least elevation of the water surface in the reservoir was chosen as representing the actual condition which would obtain. For comparing these calculations with results obtained by Mr. Casler's method, the writer's computation will be presented first.

A longitudinal section through the dam, power house, and channels is shown in Fig. 11. As an aid to calculation, curves of the hydraulic radius and the area of each cross-section were plotted, but are not reproduced.

Various constants were adopted as follows:

- (1) At the entrance,  $A$ , three piers project inward. The coefficient for entrance loss,  $K_e$ , was therefore taken as 0.78.\*
- (2) For the loss due to obstruction and sudden contraction at  $F$ , the factor, 0.25, was assumed.
- (3) The coefficient,  $n$ , for friction or rough concrete was taken as 0.015.†

Further, a curve was plotted for determining the coefficient,  $C$ , for various values of hydraulic radius,  $r$ , when  $S = 0.001$  and  $n = 0.015$  for a rough concrete channel. The values of  $C$  for a given  $r$  vary little between the limits,  $S = 0.0004$  and  $S = 0.01$ ; so that using values of  $C$  when  $S = 0.001$  (or 0.0004 or 0.01) does not materially affect the answer if the actual water slopes are within those limits.

Using these various curves, Table 9 was prepared, showing the various trial computations. Many of the notations and derivations will be apparent from Fig. 11. The terms,  $A$ ,  $v$ ,  $h$ ,  $r$ ,  $l$ ,  $S$ , and  $H$ , give the area, velocity, velocity head, hydraulic radius, length of channel, hydraulic slope, and differential head, respectively. The subscripts refer to the parts of the channel concerned, as follows: 1, for Point  $G$ ; 2 for the reach,  $GF$ ; 3, for Point  $F$ ; 4 for Point  $E$ ; 5 for the reach,  $E-D$ ; 6 for Point  $D$ ; 7 for Point  $C$ ; 8 for the reach,  $C-B$ ; and 9 for Point  $B$  (all these points are numbered to correspond in Fig. 11).

The values of "Water Elevation" (Table 9, Columns (1), (6), (15), (24), (31), etc.) are assumed in each case, whereas other "computed elevations" (Columns (22), (30), etc.) are derived from the tubular values. Ordinarily, for the first trial, the elevation in Column (22) will not check that assumed in Column (15). The values given are for the final results and similarly for the other reaches.

Then, the curve in Fig. 12 was plotted from Column (73), Table 9. Evidently, the minimum elevation of the water surface is at Elevation

\* See King's Handbook, p. 152.

† Loc. cit., p. 191.

436.95. This same process may be repeated for other discharges,  $Q$ , of 500, 1000 sec.-ft., etc., which will give the data for plotting another curve which would show the discharge through the channel for various elevations of the water surface in the reservoir.

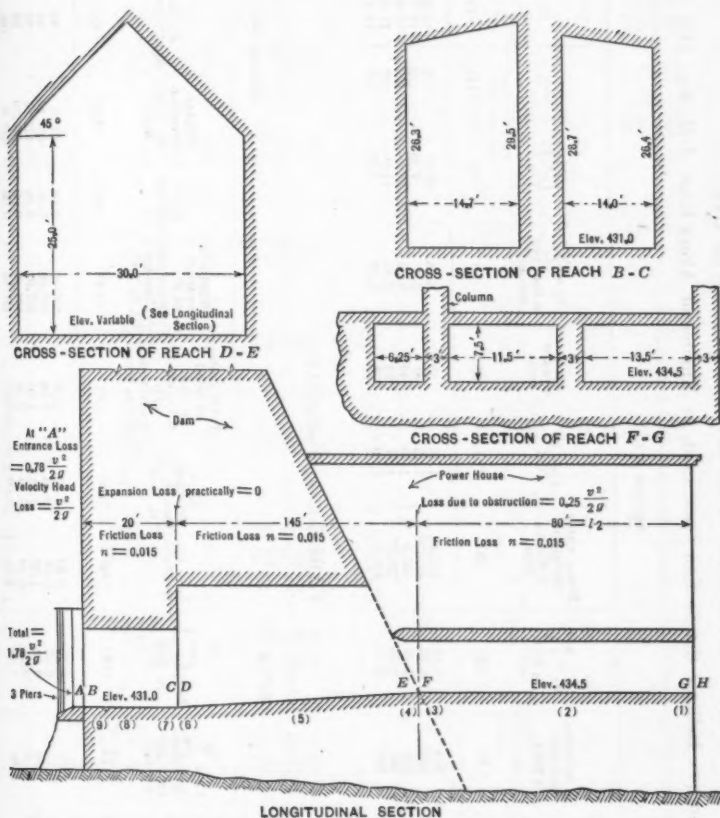

FIG. 11.—SECTIONS OF FLOOD CONTROL CHANNEL, THROUGH DAM AND POWER HOUSE.

A check will now be applied to those calculations using Mr. Casler's method, to compare not only the results, but also the advantages and time saving. Fig. 13, showing values of  $Q$  and  $f$  for Section F-G, is plotted from values computed according to the author's method, for  $Q = 300$  sec.-ft. Similar curves were plotted for each of the other two sections, but are not presented.

By inspection, it is probable that the critical section is at (or near) the lower end. If it is, then the procedure would be as follows.

## 1.—Determination of Water Depth at Critical Section.—

$$\frac{a^3}{b} = 0.0311 Q^2 = 2799$$

$$\frac{a^3}{b} = b^3 \times \frac{d^3}{b} = b^2 \times d^3 = 2799$$

but,

$$b = 31.25, \text{ and } b^2 = 976$$

therefore,

$$d^3 = \frac{2799}{976} = 2.87$$

or,

$$d = 1.42$$

$$h = \frac{d}{2} = 0.71$$

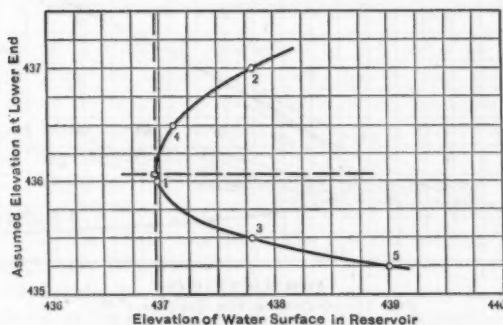

FIG. 12.—CURVE SHOWING MINIMUM ELEVATION OF WATER SURFACE IN RESERVOIR. PLOTTED FROM TABLE 9.

Therefore,

$$(d + h) = 2.13$$

Then the elevation of the water surface at *G*, is,

$$434.50 + 1.42 = 435.92$$

The value of *f* may be found from the formula,  $f = \frac{p g}{b C^2}$ . Since,

$$p = 31.25 + (6 \times 1.42) = 39.77$$

$$b = 31.25$$

and,

$$C = 115$$

$$f = 0.0031$$

2.—Consideration of Reach *G-F*.—The fundamental hydraulic relation between two planes, *X* and *Y* (Fig. 10), is:

$$(d_x + h_x) - \frac{l}{2} f_x = (d_y + h_y) + \frac{l}{2} f_y - l i$$

In this case:  $l = 80$ ;  $f_y = 0.0031$ ;  $i = 0$ ; and  $(d_y + h_y) = 2.13$ .

Thus,

$$(d_x + h_x) - 40 f_x = 2.13 + (40 \times 0.0031) - 0 = 2.25$$

but  $f > i$ ; therefore, follow the  $Q$ -curve upward from the vertex (Fig. 13).

After successive trials, assume that  $(d_x + h_x) = 2.31$ . Then, from Fig. 13,  $f_x = 0.0015$ , and  $40 f_x = 0.06$ ; or  $2.31 - 0.06 = 2.25$  (which checks, as it should).

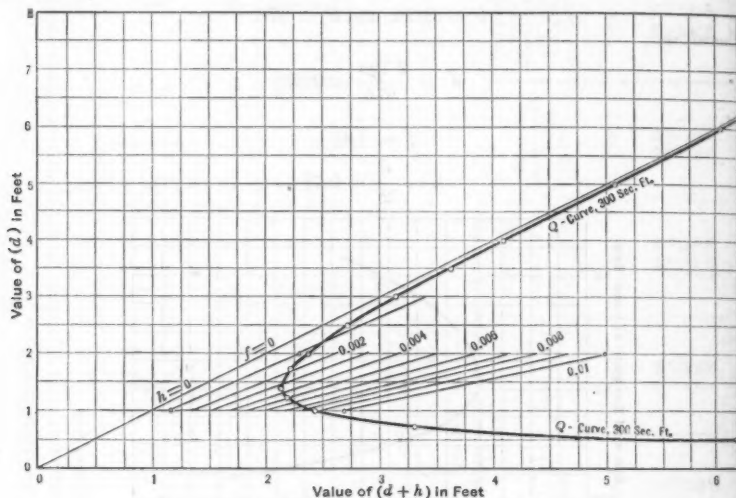

FIG. 13.— $Q$ -CURVES FOR SECTION F-G.

Then,

$$(d_x + h_x) = 2.31$$

From Fig. 13,

$$d_x = 1.90$$

or,

$$h_x = 0.40$$

$$\text{Elevation of invert} = 434.50$$

$$d_x = 1.90$$

Therefore, water surface elevation at  $F = 436.40$

3.—*Consideration of Losses at Point E-F.*—The loss due to obstruction at  $F = 0.25$  times the velocity head at the point,  $F = 0.25 \times 0.40 = 0.10$ .

As before,

$$\begin{aligned} (d_x + h_x) - \frac{l}{2} f_x &= (d_y + h_y) + \frac{l}{2} f_y - l i + \text{other losses} \\ &= 2.31 + 0 + 0 + 0.10 = 2.41 \\ i &= 0, \end{aligned}$$

and,

$$f = 0.0015$$

As  $f > i$ , follow the  $Q$ -curve upward from the vertex. Since  $l = 0$ ,

$$(d_x + h_x) = 2.41$$

From a curve for Section *D-E* (similar to Fig. 13),  $d_x = 2.03$  ft., and  $f_x = 0.001$ . Then,

Elevation of invert at *E* = 434.50

$$d_x = 2.03$$

Therefore, elevation of water surface at *E* = 436.53

In a similar manner, the water surface elevations (and the other concurrent functions) were calculated for each section to the reservoir.

*Check on Flow at Point B*.—It was found by calculation that, at *B*,  $h = 0.05$  and  $d = 5.93$ . Therefore,

$$v = 1.79$$

$$a = 28.7 \times 5.93 = 170.5$$

$$Q = a v = 170.5 \times 1.79 = 3.05 \text{ (check)}$$

*Comparison of Results*.—A comparison of the water surface elevations at each point along the channel, calculated by the two different methods (Table 10), shows that one is a substantial check on the other. The writer's method gives a water surface elevation varying from about 0.08 ft. higher to 0.07 ft. lower than that of Mr. Casler.

*Discussion*.—Judging from experience in calculations of this kind, evidently Mr. Casler's method is much shorter and more direct, and gives a clearer vision of the whole problem. The writer's method is one of trial and error, and is very laborious.

In many hydraulic problems, the critical section may be located from a superficial glance at the physical conditions. After this section is determined, the solution, by Mr. Casler's method, is almost entirely direct.

TABLE 10.—COMPARISON OF RESULTS BY TWO METHODS.

Point.	ELEVATION OF WATER SURFACE.		Difference from Casler's method.
	Casler's method.	Writer's method, using Chezy formula.	
<i>G</i>	435.92	436.00	+0.08
<i>F</i>	436.40	436.46	+0.06
<i>E</i>	436.53	436.58	+0.05
<i>D</i>	436.93	436.89	-0.04
<i>C</i>	436.93	436.88	-0.05
<i>B</i>	436.93	436.88	-0.05
<i>A</i>	437.02	436.95	-0.07

It will be noticed that Reach *F-G* is a three-barreled conduit, and that these calculations assume that the water surface elevation will be the same in all three. Actually, this will not happen, for the hydraulic radii are not the same, and, therefore, the friction loss will differ. If one cared to follow out the calculations, considering each barrel separately, it could be done, but the practical difference would be negligible.

F. THEODORE MAVIS,\* Assoc. M. Am. Soc. C. E. (by letter).—The author's use of the term, "friction factor", for the slope of the energy line is confusing since that term has long been used in referring to the measure of channel roughness, particularly in formulas for flow of fluids in pipes. The friction factor,  $f$ , in the Chezy formula,  $h = f \frac{l}{d} \frac{v^2}{2g}$ , is a function of the Reynolds number,  $\frac{vd}{\nu}$ , and the character of the conduit, and it is not the slope of the energy line,  $\frac{h}{l}$ . ( $h$  is the loss in energy head in a distance,  $l$ ;  $d$ , the diameter of the conduit;  $v$ , the velocity; and  $\nu$ , the coefficient of kinematic viscosity divided by its density.† Many texts refer to the slope factor in the Chezy formula and its subsequent modifications as the slope of the water surface, although this definition leads to inconsistencies which are clarified if  $S$  is defined as the slope of the total energy line.

The author states that,

"Equations (10) and (11) are applicable to any invert profile and to any shape of channel section, constant or variable, open or closed, flowing freely or under pressure. \* \* \* From Equations (10) and (11), the energy gradient \* \* \* can be computed for any given channel for an assumed  $Q$ ."

These equations, which are identical, are merely expressions of Bernoulli's theorem which states that the difference between the total energy  $\left( \frac{p}{w} + z + \frac{v^2}{2g} \right)$ , at two points on a given stream line is equal to the losses of energy between those two points. If this theorem is to be applied to any variable section one must know not only the amounts of various energy losses, but also the pressure and velocity distributions, in order to arrive at even an approximate solution of a given problem. With regard to the second part of the author's statement it may be said that nothing has been presented in the paper which will allow one to calculate the energy gradient and hydraulic gradient for flow in a rectangular channel of uniform section, in which the flow changes from torrential flow (less than critical depth) to ordinary turbulent flow (greater than critical depth), even if one neglects perimeter friction and assumes constant velocity in a given cross-section of the stream.

The writer does not agree with the statement made in the first part of "Criterion (3)", namely,

"The general criterion for selecting the correct value of  $d$  as between these two mathematical possibilities is as follows: The water will flow at such a depth,  $d$ , that the lost head,  $F$ , between any two sections will be as nearly as possible equal to the invert drop,  $I$ , in that same stretch of channel. \* \* \*

\* Asst. Prof., Mechanics and Hydraulics, Univ. of Iowa, Iowa City, Iowa.

† See Walker, Lewis, and McAdams, "Principles of Chemical Engineering" (McGraw-Hill Book Co.), for values of  $f$  as a function of the Reynolds number.

Except in the very special case of steady flow at constant depth in an open channel with a uniform section, there is absolutely no general relation between the slope of the energy line and the slope of the invert of the channel. Assume, for instance, that the slope of the invert of a rectangular channel increases from 1 to 10% (in the direction of flow). The slope of the energy line below the point of intersection of these grade lines may be greater or less than the slope of the line above that point, depending on whether the water is accelerated on the steeper slope or whether it is decelerated so that the depth of flow becomes greater and greater.

The last sentence of Criterion (3), "successive values of  $(d + h)$  will be as nearly as possible equal to each other", is ambiguous and would easily lead to the erroneous impression that the height of a hydraulic jump is the difference between corresponding depths of flow,  $d$ , for the same total energy  $(d + h)$  as shown in the author's diagrams.

The author has stressed the energy equations of one-dimensional flow and has made no mention of the impulse and momentum equations. The latter are often indispensable in arriving at quantitative values of head losses, for instance, at sudden enlargements in section or at a hydraulic jump. These equations follow directly from the fundamental law of mechanics,

$$\frac{d}{dt} (m v) = F \dots \dots \dots (62)$$

Since the mass of water moving between two cross-sections of a channel is,

$$m = \frac{Q w}{g} d t$$

and, assuming steady flow,  $Q$  is constant,

$$\frac{d (m v)}{d t} = \frac{Q w}{g} (v_1 - v_2) = F \dots \dots \dots (63)$$

in which,

$Q$  = rate of discharge;

$w$  = weight of a unit volume of water;

$g$  = acceleration of gravity;

$v_1$  and  $v_2$  = velocities at Sections 1 and 2, respectively; and

$F$  = the resultant of forces acting on Sections 1 and 2.

Finally, if  $b$  is the width of the water prism at a depth,  $z$ , below the free surface of the water and  $d_1$  and  $d_2$  are the depths of flow at Sections 1 and 2,

$$F = w \int_0^{d_2} z b d z - w \int_0^{d_1} z b d z = \frac{Q w}{g} (v_1 - v_2) \dots \dots \dots (64)$$

For a rectangular channel of constant width,  $b$ ,  $\left( v_1 = \frac{Q}{b d_1}, v_2 = \frac{Q}{b d_2} \right)$ , Equation (64) (dividing through by  $w$ ) becomes,

$$d_2^2 - d_1^2 = \frac{2 Q^2}{b g} \left( \frac{1}{d_1} - \frac{1}{d_2} \right)$$

or,

$$d_1 d_2 (d_1 + d_2) = \frac{2 Q^2}{b g} \dots \dots \dots (65)$$

Equation (65) expresses the relation between the depths,  $d_1$  and  $d_2$ , above and below a hydraulic jump\* in a rectangular channel assuming "one-dimensional" flow and neglecting friction along the walls of the channel. The energy loss due to the jump is, therefore,  $\left(d_1 + \frac{v_1^2}{2g}\right) - \left(d_2 + \frac{v_2^2}{2g}\right)$ .

One would infer from the treatment of the critical section and from Criterion (4) that a critical stage must be found in a given channel before the calculations of flow referred to by the author can be made. In any given problem which is capable of solution, if the depth of flow, the discharge, and the properties of the channel are known at any point the computations referred to can be carried through for conditions of one-dimensional flow. It happens that, at a critical section, the depth of flow is determinable, but the existence of a section where the velocity passes through the "critical" is rather the exceptional than the usual case. If the velocities exceed the critical, that is, if a critical section exists, the computer will have need for other tools in addition to Equations (10) and (11).

The only difficulties in problems of one-dimensional flow are to find the magnitude of the losses. With the possible exception of shock losses at sudden enlargements of section, which the writer has mentioned, the solution of these difficulties can be found only by experiment. The results of many experiments (for example, experiments on flow of water in pipes and open channels, flow through orifices and over weirs), have been generalized so that they can be used readily. Only elementary mathematical tools are necessary in solving problems of one-dimensional flow.

By no means, however, may all the problems of flow in open channels be considered to be one-dimensional flow problems even for purposes of engineering design. If the problem is one of two or three-dimensional flow the engineer will probably avoid the methods of mathematical hydrodynamics in its solution and rely almost wholly on experimental methods. Model experiments in the hydraulic laboratory should be emphasized as one of the most useful methods and one generally applicable for studying those problems of hydrodynamics and stream flow which thus far have defied mathematical analysis.

\* MORROUGH P. O'BRIEN,† Assoc. M. Am. Soc. C. E. (by letter).—Although at first glance, Mr. Casler's method of computing non-uniform flow seems to be quite simple, it is, with its several criteria, more complicated to apply than the methods of many other writers who have treated the subject, notably Flamant,‡ A. H. Gibson,§ and more recently Tylvad,|| Schonweller,¶ Böss,\*\*

\* For data on hydraulic jump phenomena, see, Julian Hinds, M. Am. Soc. C. Koch,\* and Lindquist.† Of the formulas proposed probably the most general is that of Lindquist for channels of constant cross-section:

$$d(d) = \frac{1}{2} \frac{\zeta_n \left(\frac{d}{d_n}\right)^3 - \zeta}{\left(\frac{d}{d_c}\right)^3 - 1} d l \dots \dots \dots (66)$$

This includes all the necessary criteria since  $d_n$  is the depth for normal or uniform flow,  $d_c$  is the critical depth, and  $\zeta_n$  and  $\zeta$  are factors depending on the slope of the energy gradient at uniform flow, and at the flow considered, respectively. The values of  $\zeta$  to be used are to be obtained from the formulas:

$$\zeta = \frac{2g}{\sqrt[3]{R} M^2}$$

for the higher alternate stage, and,

$$\zeta = a + \frac{b}{\sqrt[3]{\frac{Rv}{\nu}}}$$

for the lower alternate stage.

The constants,  $M$ ,  $a$ , and  $b$ , are to be found in special tables† and  $\nu$  is the kinematic viscosity. The differentiation between the frictional losses at the higher and lower stages of flow resulted from a study of some of Bazin's experiments, which showed that the manner of flow was essentially different at the two stages and that at the lower stage the loss is practically the same as for the towing of flat plates held parallel to the direction of motion.‡

An even more general formula is that of Freytag which includes terms representing the change in the bottom width and the side slope,

$$\frac{dz}{dl} = \frac{v^3}{C^2 R} \mp \frac{Q^2}{g a^3} \cdot \frac{\delta a}{\delta c} \times i \mp \frac{Q^2}{g a^3} \left( \frac{\delta a}{\delta \alpha} \times \frac{d \alpha}{d l} + \frac{\delta a}{\delta b} \frac{d b}{d l} \right) \dots \dots (67)$$

$$1 \mp \frac{Q^2}{g a^3} \cdot \frac{\delta a}{\delta d}$$

in which,

$\alpha$  = the side slope;

$b$  = the width of the bottom; and

$z$  = the elevation of the water surface.

The negative sign is to be used for accelerated, and the positive sign for decelerated, flow.

Although Equations (66) and (67) appear to be far more complicated than those given by Mr. Casler, they are equally simple to apply since in a practical case the differentials could be replaced by finite increments. They have the advantage that in some cases all the variable quantities can be

\* Koch and Carstanjen, "Bewegung des Wassers," Berlin, 1926.

expressed in terms of the distance\* and the exact equation for the water surface can be obtained by integration.†‡

The author indicates a very common error in the use of the Chézy-Eytelwein equation, namely, that the slope to be used is either the slope of the bottom or of the water surface. However, even when this slope factor is correctly taken to be the slope of the energy gradient, the question arises as to whether the same coefficients may be used in computing it for non-uniform flow. Böss§ made a few experiments on this problem and found that for both accelerated and decelerated flow, the coefficient,  $n$ , in the Kutter formula was the same, but his experiments were few in number and were made in a very small channel. It would seem that for an equal mean velocity in the same channel, the drop in the energy line would be greater during decelerated than during accelerated flow. In his method of computation, Koch includes an impact loss for decelerated flow.

In most computations of flow, the velocity head is based on the mean velocity without making a correction for the effect of the unequal distribution of velocity. The exact expression for  $h$  is,

$$h = \alpha \frac{\bar{v}_m^2}{2g} = \frac{\int_0^A \rho v^3 da}{2g \int_0^A \rho v da} = \frac{\int_0^A \rho v^3 da}{2g \cdot \rho \bar{v}_m A}; \alpha = \frac{\int_0^A v^3 da}{\bar{v}_m^3 A} \dots \dots (68)$$

in which,

$\rho$  = the density;

$v$  = the velocity over a small element of area,  $da$ ;

$A$  = the total area of the cross-section; and

$\bar{v}_m$  = the mean velocity.

in channels in which the distribution of velocity is determined by the friction at the walls and not by obstructions.

If it is necessary that  $\alpha$  be included, an average value of 1.15 may be used. For the Bazin experiment (Table 11), an error of about 6% would have occurred in  $(d+h)$ , if  $\alpha$  had been neglected, but for the Nikuradse experiment, the error would have been inappreciable. If the flow is disturbed by sills or other obstructions,  $\alpha$  may have a value of 2 or even more.

Although the expression for the critical depth may be obtained directly from such general formulas as those of Gibson and Freytag\* from the condition of a vertical water surface, the usual method is to base it on the condition of a maximum discharge for a certain energy content, as was done by the author. The total energy passing any section in unit time is,

$$E_s = \frac{\alpha \rho Q^3}{2 a^2} + \rho g d Q \dots \dots \dots (69)$$

in which, the datum for the potential energy is the lowest point in the section considered. Expressing the width of the channel as  $b = F(d)$ , the general condition for the critical depth is,

$$F'(d) = \frac{\left[ \int_0^d F'(d) d(d) \right]^3 g}{\alpha Q^2}$$

or,

$$b = \frac{a^3 g}{\alpha Q^2}$$

For a channel of rectangular section this gives,

$$d_c = \sqrt[3]{\frac{\alpha Q^2}{g b^2}}$$

and for a parabolic section,

$$d_c = \sqrt[3]{\frac{\alpha Q^2}{\frac{8}{27} p^2 g}}$$

in which,  $p$  is the constant of the parabola.

However, this derivation does not seem to be rigorously correct since it assumes that the potential and kinetic energy are mutually convertible and that the water surface remains horizontal in passing a controlling section. Considering any transverse section of a stream, the height of the energy line is a maximum somewhere near the center; is at nearly the same height over most of the width; and drops abruptly to the water surface at the banks. The available energy of any vertical water column is the vertical distance from the energy line to the bottom and not the vertical distance to the lowest point in the cross-section. Consequently, it would seem that, under some conditions, the critical depth might not occur at all points of a cross-section.

A very simple method of representing the relation between the height of the energy line and the quantity of flow has been developed by Koch.†

\* L. Freytag, "Der Wasserabfluss in Flossgassen u. ähnlichen Gerinnen," *Forschungsarbeiten*, Heft 235, V. D. I., Berlin.

† Koch and Carstanjen, "Bewegung des Wassers," Berlin, 1926.

From the equations for the critical depth and the flow at any depth, the relation,

$$\frac{Q}{Q_{\max.}} = \sqrt{\frac{27 \alpha_{\max.} (1-n) n^2}{4 \alpha}} \dots \dots \dots (70)$$

may be obtained in which it is assumed that  $(h + d)$  is a constant of known value. The quantity,  $n$ , is the ratio,  $\frac{d}{(h + d)}$ ;  $\alpha_{\max.}$  and  $\alpha$  are the correction factors used in computing  $h$  at the critical depth and the depth considered, respectively. The following tabulation gives the values of  $n$  and the ratio,  $\frac{Q}{Q_{\max.}}$ :

$n$ .	$\frac{Q}{Q_{\max.}}$	$n$ .	$\frac{Q}{Q_{\max.}}$
0.00 .....	0.00	0.67 .....	1.00
0.1 .....	0.247	0.8 .....	0.930
0.2 .....	0.465	0.9 .....	0.740
0.3 .....	0.660	0.95 .....	0.551
0.4 .....	0.806	1.00 .....	0.00
0.5 .....	0.919		

Plotting these values along a vertical line between  $(d + h)$  and  $d = 0$  gives a diagram which is very convenient in studying the flow through constricted sections, especially where the change in the area of the stream is very abrupt, as at bridge piers and broad, submerged weirs.

In the application of his method to the computation of the coefficients of discharge of weirs and orifices, the author makes several assumptions that are not correct. He assumes, for instance, that the velocity is uniform throughout the section above the crest of a sharp-crested weir; that the critical depth occurs above the crest of a weir; and that at a section,  $y$ , beyond an orifice, the thickness of the jet may be used as  $d_v$  in Equation (42).

Table 12 gives values of the head, depth over the crest, and critical depth for the weir shown in Fig. 14, which was tested in the Hydraulic Structures Laboratory of the Royal Technical University at Stockholm, Sweden.

TABLE 12.—TEST ON WEIR AT ROYAL TECHNICAL UNIVERSITY, STOCKHOLM, SWEDEN.

$H$ , in meters.	$Q$ ( $\frac{m^3}{\text{sec}}$ ).	$d_c$ , in meters.	$d$ (crest), in meters.	$\mu$ .
0.05	0.021	0.085	0.04	0.686
0.15	0.110	0.135	0.122	0.686
0.25	0.242	0.180	0.22	0.649
0.40	0.425	0.2685	0.34	0.677

The critical depth is seen to be considerably less than the depth over the crest. In Figs. 14 and 15, the horizontal lines are 5 cm., and the vertical lines are 10 cm., apart. In Fig. 14,  $H = 0.25$  m.,  $Q = 0.242$  cu. m. per sec.

per meter of crest, and  $d_c = 0.180$  m. Fig. 15, in which  $Q = 0.080$  cu. m. per sec. per meter of crest, shows one of a series of experiments on the discharge coefficients of broad-crested dams. The critical depth, which was about 0.0863 m., occurs 14 cm. from the down-stream end of the crest. An examination of other photographs from this series of experiments showed that for this particular dam the critical depth occurs at approximately the same point for all discharges within the range of the experiments.

If the critical depth is uniquely defined by the discharge, then it is permissible to state that the depth over the crest of a weir is a critical depth. However, this critical depth is not the same as that used in open channels where the paths of the fluid particles are sensibly parallel.

There does not seem to be any lack of methods for computing non-uniform flow in conduits, but rather a lack of sufficient coefficients for computing losses due to impact and friction and data regarding the formation of jumps, bores, and other phenomena. Since Bazin's experiments there have been some additions to the available information made by American and European laboratories, but it is insufficient and even what has been done, is not widely known. This problem should be carefully studied in a laboratory by means of small-scale experiments supplemented by measurements of large-sized streams and canals. The establishment of a National hydraulic laboratory would provide the means for the study of this and hundreds of other similar problems and would help to remove much of the uncertainty which now arises in nearly all hydraulic computations.

R. D. N. SIMHAM,\* Assoc. M. Am. Soc. C. E. (by letter).—This paper furnishes a broad and concise outline of many complex but closely inter-related factors to be considered in determining flow in channels, etc. The whole question is of great importance; and the fact that engineers are accustomed to apply the results of small laboratory experiments to the calculation of large works, without actually knowing the general law, and without, in fact, making proper allowances for the results obtained, makes it imperative that the question should be thoroughly investigated in the light of modern hydrostatic and hydrodynamic theories. Probably no radical advance in the theory or practice of experimental hydraulics will be made until the general question concerning the motion of water in channels, conduits, etc., is correctly solved.

For some time, the writer has been studying this problem seriously and in many ways he finds that his results and conclusions coincide fairly well with those of the author.

*Derivation of the Chezy Formula.*—The author assumes, as usual, that the unit of frictional resistance is proportional approximately to the square of the velocity. His assumption that the total frictional resistance of a quantity of water flowing for 1 sec. and moving forward 1 ft. is  $K p v^3$  and that the energy consumed in the same is also  $K p v^3$ , although it would appear to be mathematically infallible, still conveys no practical idea. The value,  $K p v^3$ , which is the loss of energy due to frictional resistance against the kinetic

\* Town Planning Asst., Madras, India.

motion of water, should, in fact, be equal to  $\frac{W}{2g} (v_x^2 - v^2)$  when  $S = 0$  and  $v_x$  represents velocity at a section 1 ft. back; then:

$$K p v^3 = \frac{W}{2g} (v_x^2 - v^2) \dots \dots \dots (71)$$

Also,

$$K p v^3 = \frac{w a v}{2g} (v_x^2 - v^2) \dots \dots \dots (72)$$

By simplifying Equation (72) and transposing terms,

$$v_x^2 = v^2 \left( \frac{2 K p g}{w a} + 1 \right) \dots \dots \dots (73)$$

and when  $v_x = \sqrt{2} v$ ,  $2 K p g = w a$ , and thus,

$$K = \frac{w a}{2 g p} \dots \dots \dots (74)$$

Substituting Equation (74) for the value of  $K$  in Equation (1) and solving for  $v$ , the result is:

$$v = \sqrt{2 f g} \dots \dots \dots (75)$$

that is,

$$C = \sqrt{\frac{2 g}{r}} \dots \dots \dots (76)$$

Obviously, Equation (76) does not take into account any constant for friction; hence, in a case like the foregoing the author's result appears to be incomplete.

Nearly all formulas for velocity are identical in that the hydraulic radius and the sine of the angle of inclination of the stream flow are both functions of the velocity, and are generally reducible to the elementary form,  $v = C \sqrt{r f}$ . Although it is far from complete, the following list gives some of the values of  $C$ , as used by various authorities in particular cases: Chezy, 100; Downing, 100; Leslie, 100 and 68; Taylor, 100; Pole, 100; Blackwell, 95.8; Hawksley, 96.1; Bartlet, 95.9; Young, 84.3; Kirkwood, 80.0; d'Aubisson, 100 and 68; Beardmore, 100 and 94.2; Neville, 93.3 and 92.3; Stevenson, 96.0 and 69.0; and Eytelwein, 100.0 and 93.4.

Even all the more complex expressions for velocity can be reduced in some way to the terms of the simple formula,  $v = C \sqrt{r f}$ , in which it will appear that the factors,  $v$ ,  $\sqrt{r}$ , and  $\sqrt{f}$ , all bear a consistent relation one to another, and that the coefficient,  $C$ , is really the involved factor through which the value of  $v$  is independently modified. To make this clear, note that the complex terms within the brackets in D'Arcy's formulas, Kutter's formula, and Bazin's formulas are the only features in which any of these expressions differ; in short, the involved term in each case only expresses the value of  $C$  as a coefficient of flow. The factors,  $r$  and  $f$ , are usually determined by observation, while on the other hand the coefficient,  $C$ , is empirical in character

and its values, as used in the respective formulas, are presumed also to have been determined by experiment. In all the equations for velocity,  $C$  is the vulnerable factor and through it are introduced all the serious discrepancies that appear.

When a body, whether solid, liquid, or gaseous, is caused to slide over a surface of another, or pass through a solid enclosure, a resistance to sliding or motion is experienced which is known as the friction between the two bodies. Proceeding on this definition, the following laws of friction may be stated:

1.—Frictional resistance is proportional to the coefficient of friction applied to the surface of contact or the solid enclosure.

2.—Fractional resistance varies directly as the resultant head contributing to the movement of water, which is sometimes represented as equal to the square of the velocity of flow; and

3.—Frictional resistance is proportional to the area of the wetted surface past which the water flows.

These assumptions lead to the general relation expression:

$$l p c w (H - F) = w F a \dots \dots \dots (77)$$

in which,  $(H - F)$  is the total resultant kinetic head;  $l$  is the length of the channel; and  $c$  is the coefficient of friction. Therefore,

$$F = \frac{c l}{r} (H - F) = \frac{H}{\left(\frac{r}{c l} + 1\right)} \dots \dots \dots (78)$$

Furthermore,

$$v = \frac{\sqrt{2 g}}{\sqrt{c l}} \sqrt{r F} \dots \dots \dots (79)$$

Assuming that the friction head is lost at a uniform rate,

$$r = \frac{\sqrt{2 g}}{\sqrt{c}} \sqrt{r f} = C \sqrt{r f} \dots \dots \dots (80)$$

$$\text{in which, } C = \frac{\sqrt{2 g}}{\sqrt{c}}.$$

When the assumption is made that the gradient factor in the Chezy formula represents either the hydraulic gradient or the invert gradient, the question of applying the formula is abortive, or assessing the value of  $C$  is rendered practically difficult. Perhaps the proper value of the coefficient in any particular case cannot be determined by calculation or by any arbitrary rule. Presumably, even the modern complicated expressions used to determine the value of  $C$  will not faithfully take into account all the factors that influence the flow of water. In hydraulic problems, no doubt, one can hardly hope to express a complex proposition clearly with a simple formula, and, for that reason, all critical and trustworthy equations relating to the flow of water are, of necessity, somewhat involved.

If the gross energy head,  $H + d$ , equals  $M$ , and the net kinetic head,  $H - F$ , equals  $D$ , then substituting these values in Equation (78):

$$F = \frac{c l}{r} D = \frac{M - d}{\frac{r}{c l} + 1} \dots\dots\dots (81)$$

The gross kinetic head is,

$$H = D \left( 1 + \frac{c l}{r} \right) \dots\dots\dots (82)$$

The net kinetic head is,

$$D = \frac{H}{\frac{c l}{r} + 1} \dots\dots\dots (83)$$

The maximum resultant velocity is:

$$\sqrt{2 g D} = \sqrt{\frac{2 g H}{\left( \frac{c l}{r} + 1 \right)}} \dots\dots\dots (84)$$

The maximum discharge is:

$$Q = a \sqrt{\frac{2 g H}{\left( \frac{c l}{r} + 1 \right)}} \dots\dots\dots (85)$$

Based on Equations (81) to (85), other equations for the critical values applied to rectangular sections (which may be compared with those of the author) may be written as follows:

(a) When  $a$ , the cross-section of the stream, is constant, the equations at

the critical-economic section ( $b = 2 d$ ) take the form,  $v = \sqrt{\frac{2^{\frac{3}{2}} g H a^{\frac{1}{2}}}{(\sqrt{2 a + 3 c l})}}$ ,

and  $Q = \sqrt{\frac{2^{\frac{3}{2}} g a^{\frac{5}{2}} H}{(\sqrt{2 a + 3 c l})}}$ . Under these conditions, when  $l = 0$ ,  $v = 6.755 H^{\frac{1}{2}}$

and  $Q = 6.755 a H^{\frac{1}{2}}$ , respectively.

At the critical-efficient section ( $D = \frac{d}{4}$  and  $b = 2 d$ ),  $v = \sqrt{\frac{2}{2^{0.25} a^{0.25}}}$ ;  $Q = \frac{g^{0.5} a^{1.25}}{2^{0.75}}$ ; and  $F = \frac{3 c l}{8}$ .

(b) Generally, when  $b = n d$ ,  $D = \frac{d}{4}$ ;  $v = 4.013 \left( \frac{a}{n} \right)^{0.25} = 4.013 a^{0.5} \text{ and,}$

$$Q = a \sqrt{\frac{g d}{2}} = 4.013 a a^{0.5} = 4.013 \frac{a^{1.25}}{n^{0.25}} \dots\dots\dots (86)$$

These will apply to channels of triangular section and trapezoidal section with some modification.

(c) When  $b$  is constant,  $D = \frac{d}{2}$ , and,

$$v = \sqrt{g d} = 5.674 \sqrt{d} \dots\dots\dots (87)$$

Then,

$$Q = g^{0.5} b d^{1.5} = 5.674 b d^{1.5}$$

$$d = \frac{Q^{0.67}}{2^{0.33} b^{0.67}}$$

and,

$$F = \frac{c l (b^{1.67} g^{0.33} + 2 Q^{0.67})}{2 g^{0.33} b^{1.67}} \dots \dots \dots (88)$$

With reference to Equation (87), there are data available to show how certain canals in America have not scoured appreciably even under relatively high velocities. The magnitude of these velocities is known from measurements of the canals, but the exact value of  $v$  that would start the scour has never been determined. Presumably, a higher velocity is required to start the banks to scour than to continue it when once started, as illustrated by the fact that certain canals do not scour even if the mean velocity is several times that suggested by Dubuat or Kennedy. The value given by Equation (87) seems to determine the greatest velocity (which is also the economical velocity) that a particular canal would stand before beginning to scour (see Table 13).

TABLE 13.—SCOUR OBSERVATIONS TO DETERMINE SCOURING EFFECTS  
IN THE GREAT MIAMI VALLEY.

Location.	Recorded mean depth, in feet.	Recorded maximum average velocity, in second-feet.	Computed velocity from Equation (87) assuming rectangular section.	Results.
"Big Four" Railroad Bridge, Buck Creek.....	6.7	13.7	14.7	No scour
"Big Four" Railroad concrete arch, Tawara Creek, east of Sidney.....	8.2	23.1	16.2	Scour
Seven-Mile Creek, Ohio.....	2.58	5.44	9.1	No scour
Miami River cut-off channel.....	1.8	5.5	7.6	No scour

Equations for the critical values applied to conduits with circular cross-sections flowing full may be written as follows:  $D = \frac{d}{4}$ ;  $Q = 3.149 d^{2.5}$ ; and the economical diameter, for any discharge, equals  $d = \frac{Q^{0.4}}{3.149^{0.4}} = 0.633 Q^{0.4}$ .

The economical velocity equals,

$$v = 2 g D^{0.5} = 4.01 d^{0.5} \dots \dots \dots (89)$$

Formulas for critical net energy head are:  $d + D = 0.791 Q^{0.4}$ ;  $H =$

$$0.158 Q^{0.4} + \frac{c l}{4}; M = 0.791 Q^{0.4} + \frac{c l}{4}; \text{ and } F = c l.$$

Table 14 shows how the economical velocities, computed from Equation (89), compare with the values given by Fanning and Unwin.

TABLE 14.—COMPARISON OF VALUES FOR ECONOMICAL VELOCITY.\*

Diameter, in inches.	4	6	12	18	24	36
Equation (89).....	2.3	2.8	4.0	4.9	5.6	6.9
Fanning.....	2.5	2.8	3.5	4.5	5.3	7.0
Unwin ( $V = 1.45 d + 2$ ).....	2.5	2.7	3.5	4.2	4.9	6.4

\* The velocity is given in feet per second.

†  $d$  = diameter, in feet.

General equations for orifices may be written as follows:

For rectangular orifices (free, as shown in Fig. 16(a)):

$$Q = \frac{8.02 b_1 d_1 (M - d_1)^{0.5}}{\left\{ 1 + \frac{2c(b_1 + d_1)}{b_1 d_1} \right\}^{0.5}} \dots (90)$$

For rectangular orifices (submerged, as shown in Fig. 16(b)):

$$Q = \frac{8.02 b_1 d_1 (M - d)^{0.5}}{\left\{ 1 + \frac{2c(b_1 + d_1)}{b_1 d_1} \right\}^{0.5}} \dots (91)$$

For circular orifices (free, as shown in Fig. 16(a)):

$$Q = \frac{6.301}{(d_1 + 4c)^{0.5}} d_1^{2.5} (M - d_1)^{0.5} \dots (92)$$

For circular orifices (submerged, as shown in Fig. 16(b)):

$$Q = \frac{6.301}{(d_1 + 4c)^{0.5}} d_1^{2.5} (M - d)^{0.5} \dots (93)$$

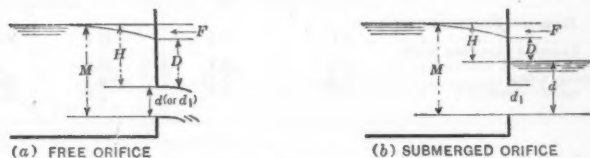

FIG. 16.

The formulas do not take cognizance of the velocity of the water approaching the orifice. Where this is appreciable it must be taken into account, and  $H$  or  $M$  would then include also the head due to the velocity of approach.

Equations for the discharge of water through pipes may be written as follows: Referring to Fig. 17, it may be seen that,  $M = H + d$ , and that,  $H = z + F_z + I + F_t = Z + I + F = D + F$ ; then,

$$Q = \frac{6.301}{(d_1 + 4c)^{0.5}} d_1^{2.5} (M - d_1)^{0.5} \dots (94)$$

General formulas may be written for weirs, as follows:

$$Q = 5.674 \left\{ \frac{3r}{3r + cl} \right\}^{1.5} b d^{1.5} \dots (95)$$

in which,

$l$  = width of the crest of the weir;

$c$  = coefficient of friction between water and masonry surface;

$b$  = length of weir;

$d$  = depth of water above crest of weir, when  $l = 0$ ;

$$Q = 3.089 b m^{1.5};$$

or, when  $l = 0$ , Equation (95) becomes,

$$Q = 5.674 b d^{1.5} \dots \dots \dots (96)$$

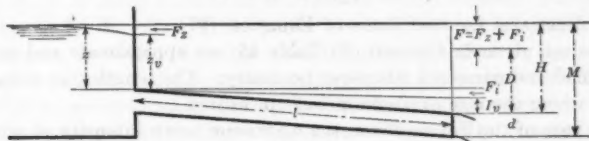

FIG. 17.

\* Site of gauge.

† Maximum width of catchment basin, in miles.

*Discharges from Catchment Basins.*—Perhaps an extension of this principle of critical discharges would facilitate the calculation of discharges in rivers. If  $d$  in. represents the maximum average concentration of rainfall or surface flow of water into the river or tributaries at any time and  $b$  ft. is the total length of the rivers and tributaries, the maximum discharge of the river may be (roughly) deduced from Equations (95) and (96). If  $d$  is in inches and  $b$  ft. = 5 280  $B$  miles:

$$Q = \frac{5.671 b d^{1.5}}{12^{1.5}}; \text{ or } 720 b d^{1.5} \dots \dots \dots (97)$$

Table 15 illustrates the usefulness of Equation (97).

The values given in Column (3) Table 15, are approximate and may have to be verified and corrected whenever necessary. The length was measured to the point where the rate of discharge was measured.

In the case of the Sonne River, the maximum mean intensity of rainfall in the basin contributing to the maximum peak on August 19, 1923, was 2.7 in.

The value of  $d$  or  $M$  would seem to depend on the intensity and duration of rainfall or to the depth of concentration of flow above ground at the river course, and the topography of the catchment basin; but the latter being a constant factor, it is probably only necessary to observe what relation actually exists between  $d$  or  $M$  and the intensity of rainfall. When that is determined the flood discharge in a river can be easily computed.

MELVIN D. CASLER,\* M. AM. SOC. C. E. (by letter).—The discussions brought forth by this paper are all very helpful in focusing attention on the fact that the consideration of "stream flow in general terms" means much more than the simple appearance of the Chezy formula would indicate.

Mr. Bailey makes the very pertinent observation that it is often of greatest importance to appreciate that a given quantity of water with a given energy content,  $d + h$ , can flow at two different depths in a given channel.

He refers to the case of an entering or discharging stream at an intersection with a branch channel. In this case, as regards sections above and below the intersection,  $Q_x$  and  $Q_y$  are unequal, and the following treatment is suggested:

Let  $Q_x'$  and  $Q_x''$  represent the respective flows of two entering streams;  $Q_y'$  and  $Q_y''$ , the respective flows of two departing streams; and,  $Q_x$  or  $Q_y$ , as the case may be, the flow at the junction. Other factors at Sections  $x$  and  $y$  are similarly indicated.  $I_1$  and  $F_1$  denote invert drop and total head loss, respectively, between the "primed" sections and the stream junction, while  $I_2$  and  $F_2$  denote the same between "double-primed" sections and the junction. Then, in the case of converging flow,  $Q_x' + Q_x'' = Q_y$ , and for diverging flow,  $Q_x = Q_y' + Q_y''$ . Following the reasoning used in the analysis of Fig. 1:

For converging flow,

$$W_x' (d_x' + I_1) + W_x' h_x' + \frac{W_x'' (d_x'' + I_2)}{+ W_x' F_1 + W_x'' F_2} + W_x'' h_x'' = W_y (d_y + h_y)$$

Replacing each  $W$  by its corresponding  $w$   $Q$ :

$$(d_y + h_y) = \frac{Q_x'}{Q_y} (d_x' + h_x' + I_1 - F_1) + \frac{Q_x''}{Q_y} (d_x'' + h_x'' + I_2 - F_2)$$

\* Mount Vernon, N. Y.

in which,

$$Q_y = Q_x' + Q_x''$$

Likewise, for diverging flow,

$$(\bar{d}_x + h_x) = \frac{Q_y'}{Q_x} (\bar{d}_y' + h_y' + F_1 - I_1) + \frac{Q_y''}{Q_x} (\bar{d}_y'' + h_y'' + F_2 - I_2)$$

in which,

$$Q_x = Q_y' + Q_y''$$

Additional terms of like form may be appended to these equations to provide for three or more tributaries or branches with a common junction.

As stated by Mr. Pearce the paper presents nothing basically new. Its prime purpose is to facilitate the analysis of stream flow in irregular channels and to present a direct method of treatment applicable to all conditions, capable of being understood and applied by the average computer, and sufficiently short to permit the inclusion of certain generally accepted principles that are usually ignored because of the laborious calculations involved in their application by current methods—most of which sacrifice accuracy for simplicity, or *vice versa*. Most existing literature on this subject is either too vague in its generalities or else it is directly applicable only to certain special cases.

As suggested by Mr. Mavis, unless the significance of the friction factor,  $f$ , is clearly recognized there may be danger of confusing the writer's  $f$  with the factor,  $f$ , in the familiar pipe formula,  $h' = f \frac{l v^2}{d 2 g}$ , in which,  $h'$  is the head loss in the length,  $l$ , due to perimeter friction, and  $d$  is the diameter of the pipe. In the writer's nomenclature,  $h' = f l$ , and, therefore, the writer's  $f$  equals the  $f$  of the pipe formula multiplied by  $\frac{h}{d}$ , in which,  $h$  is the velocity head,  $\frac{v^2}{2g}$ , and  $d$  is the pipe diameter.

With reference to Mr. Mavis' subsequent discussion it must be borne in mind that in the basic Equations (10) and (11),  $F$  is the total aggregate head loss between Sections  $x$  and  $y$ , due to all causes of whatever nature. The factor,  $f$ , is the unit head loss, due to perimeter friction only, and  $F = \int_0^l f dl + F'$ ,

in which,  $F'$  is the total head loss between  $x$  and  $y$  due to internal friction (eddies and impact due to sudden internal changes in velocity and direction). Equations (10) and (11), as stated, are theoretically correct and comprehensive and are applicable alike to one, two, or three-dimensional flows as long as  $Q$  is constant; that is, if no water enters or leaves the stream between Sections  $x$  and  $y$ .

The great obstacle in the way of the direct application of Equations (10) and (11) is the evaluation of the internal losses,  $F'$ , which must include the losses incident to two or three-dimensional flows. The factor,  $F'$ , is "the goat", so to speak, and must carry losses of sufficient aggregate magnitude to bridge all apparent discrepancies between Equations (10) and (11) and any and all observed hydraulic phenomena and experimental deductions.

At a hydraulic jump, Sections  $x$  and  $y$  are coincident and are operating at low stage and high stage, respectively;  $l = 0$ ,  $I = 0$ ,  $F = F' =$  the head loss due to the jump, and, from Equation (10),  $(d_x + h_x) - (d_y + h_y) = F'$ , which refutes Mr. Mavis' suggestion that Criterion (3) would lead to the impression that  $(d + h)$  is the same before and after the jump. Mr. Mavis overlooks the words, "as nearly as possible", in the criterion.

In the illustrative example plotted in Fig. 6,  $F'$  was ignored and, in the treatment of weirs, the entire,  $F$ , between Sections  $x$  and  $y$  was assumed as zero.

It is interesting to note that in a problem like that of Fig. 6, in which the channel is of constant cross-section, analyzed in stretches of uniform length for perimeter friction, or for any losses directly proportional to  $l$ , it is possible to eliminate all "cut and try" features by the use of a double curve as illustrated in Fig. 18. Assuming that  $F = l$  times the average  $f$  between Sections  $x$  and  $y$ :

$$F = \frac{l}{2} (f_x + f_y) \dots \dots \dots (98)$$

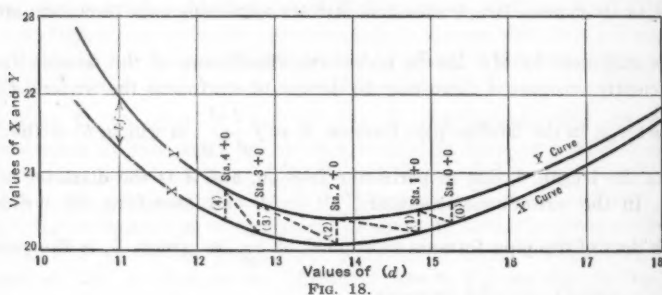

FIG. 18.

and, from the basic Equation (6),

$$d_x + h_x + I = d_y + h_y + \frac{l}{2} f_x + \frac{l}{2} f_y \dots \dots \dots (99)$$

$$d_x + h_x - \frac{l}{2} f_x = d_y + h_y + \frac{l}{2} f_y - I \dots \dots \dots (100)$$

$$d_y + h_y + \frac{l}{2} f_y = d_x + h_x - \frac{l}{2} f_x + I \dots \dots \dots (101)$$

Let  $X = d_x + h_x - \frac{l}{2} f_x$ , and,  $Y = d_y + h_y + \frac{l}{2} f_y$ . Then, if proceeding up stream,

$$X = Y - I \dots \dots \dots (102)$$

and, if proceeding down stream,

$$Y = X + I \dots \dots \dots (103)$$

The problem of Fig. 6 may now be analyzed as illustrated in Table 16.

These values of  $X$  and  $Y$  are then plotted as shown in Fig. 18. From Table 5, the value of  $d$  at Station 2 + 0 (which is the critical section (see

Fig. 6)), is 13.8. From Fig. 18, for  $d = 13.8$ ,  $X$  and  $Y$  are 20.07 and 20.44, respectively.

Proceeding up stream, the next value of  $X$  from Equation (102) is  $20.44 - 0.20 = 20.24$ , from which,  $d = 14.85$  as plotted at (1) in Fig. 18, and  $Y$  for the next up-stream stretch = 20.55. The next value of  $X$  from Equation (102) is  $20.55 - 0.20 = 20.35$ , and  $d = 15.3$  as plotted at (0) in Fig. 18.

TABLE 16.—HYDRAULIC ELEMENTS.

( $Q = 6\,000$  sec-ft.  $l = 100$  ft.)

$d$ .	$h = m^* Q^2$ .	$f = n^* Q^2$ .	$X = d + h - \frac{1}{2} f$ .	$Y = d + h + \frac{1}{2} f$ .
10.469	11.866	0.0078	21.95	22.73
11.625	9.392	0.0058	20.78	21.31
15.000	5.422	0.0030	20.27	20.57
18.000	3.787	0.0019	21.60	21.88

\* From Table 4.

Proceeding down stream from the critical section, the first  $Y$  from Equation (103) is  $20.07 + 0.60 = 20.67$ ; then,  $d = 12.8$  as plotted at (3) in Fig. 18 and  $X$  for the next down-stream stretch = 20.22. The next value of  $Y$  from Equation (103) is  $20.22 + 0.60 = 20.82$ , and  $d = 12.4$  as plotted at (4) in Fig. 18.

The dotted zigzag line in Fig. 18 thus furnishes a graphical picture and a check of the analysis presented in Fig. 6 and Table 5.

It may be pertinent to observe that while the  $f$  curves of Figs. 2 and 4 only take care of that part of  $F$  due to perimeter friction, nevertheless the  $Q$ -curves of those diagrams are comprehensive in their application to the solution of Equations (10) and (11) and are just as applicable to the consideration of internal losses or combined losses as they are to the  $f$  losses.

Fig. 6 is a case similar to the convex invert slope referred to by Mr. Mavis. Whether the water is accelerated or decelerated below the break in grade may be determined by the proper application of Equations (10) and (11).

Regarding Mr. Mavis' reference to the impulse and momentum equations it may not be over sanguine to entertain the hope that there may be found ultimately a workable method of introducing those equations in conjunction with the energy equations in such a way as to relieve the internal friction factor,  $F'$ , from some of the responsibility which it bears in Equations (10) and (11).

Mr. Mavis states in his reference to Criterion (4), that one would infer that a critical stage must be found before the calculations can be made. Such an inference was not intended. The computations may start from a critical section or from any other section where there is a condition of known depth for a known flow.

It should be noted that Criterion (3) refers only to the relations between two successive sections, one of which has already been determined, and that

Criterion (4) is merely a re-statement of Criterion (3) as applied to an analysis starting from the critical section. In the general criterion that  $F$  will be as nearly as possible equal to  $I$ , it is important to remember that  $F$  must include the losses due to any sudden changes in stage of flow.

An analysis is often started with an assumed depth at one end of the channel. If, at any stage in the progressive application of Equation (10) or Equation (11), a section is encountered at which the computed value of  $(d + h)$  is less than the critical  $(d + h)$  of that section for the assumed  $Q$ , that section is established as the critical section as regards all sections previously computed, and a new start is made at that section, revising all previous computations in reverse order.

If a known quantity is flowing at a known depth a comparison of the known  $d$  with the critical  $d$  as obtained from Equation (18) will establish the fact whether the channel at the point of known depth is operating at high stage or low stage. It may be pertinent to note that the depth of flow cannot pass from high stage to low stage, or *vice versa*, without passing through a critical section. If the transition is sudden a hydraulic jump or bore occurs, with attendant internal losses.

If, as suggested by Mr. O'Brien, there are simple, accurate methods of analysis available other than those presented by the writer, there is certainly indicated a dire need for a more general dissemination of such knowledge with illustrative examples of actual applications. All over the civilized world hydraulic engineers are daily ignoring the basic principles by applying simple approximations in the belief that more accurate analyses are impractical; or else they are laboriously plodding through reams of "cut and try" computations similar to those cited by Mr. Pearce, who demonstrates the speed and accuracy of the method of attack proposed by the writer. The only irksome feature of the writer's method is the preparation of the curves of Figs. 2 and 4 for the various sections involved. The computation of these curves and their critical factors may be readily standardized, as indicated in Tables 1, 2, 3, and 4, and reduced to systematic treatment. A computing machine is, of course, a great aid in any such operations.

Mr. O'Brien calls attention to the erroneous assumption of uniform velocity throughout the cross-section of a stream approaching a weir. This is a real error and is present in nearly all stream-flow calculations. The assumption is as stated in the definition of  $h$  in the "Nomenclature" and is again referred to in the parenthetical note following Equation (13) and the errors thus introduced are recognized and discussed in three places throughout the paper.\* The profession would owe a vote of thanks to any one who presents a practical method of taking due account of non-uniform velocities. If their effect could be evaluated there would be some hope for the universal weir diagram presented in Fig. 8.

Mr. Simham sounds a warning against the application of the results of small laboratory experiments to practical cases of large magnitude, without due consideration of the general laws involved.

\* See pp. 19-20, 22-23.

Practical experimentation is an invaluable aid in establishing coefficients and often calls attention to certain physical laws and limitations and to various practical considerations which would never have occurred to the mathematician in concocting his formulas on a purely academic basis. Nevertheless, before attempting to make general empirical application of deductions drawn from laboratory experiments, every effort should first be made to interpret fully the experiments and deduce, if possible, the basic laws operating to produce the observed results and phenomena.

The quantity,  $Kpv^3$ , referred to by Mr. Simham, is the power loss (or energy loss per second) per running foot of channel; although the writer must admit that this fact may not be apparent from the paper.

The writer's use of  $W$ , or  $Q$ , as the water unit in his derivation of the Chezy formula, Equation (1), leads to some confusion, since  $Q$  is an appreciable quantity of water spread over an appreciable length of channel throughout which  $v$  cannot remain constant under general conditions. The results are the same no matter to what quantity of water the analysis is applied, but the significance of the various factors may be more apparent from the following derivation: Let  $q$  represent a minute elemental quantity of water at any particular cross-section of the channel, expressed in cubic feet. The factor,  $f$ , is the rate of head loss per foot of channel due to perimeter friction; and hence the energy lost by the quantity of water,  $q$ , per foot of forward movement is  $w q f$  ft.-lb. (Criterion 1).

The length of channel occupied by the quantity,  $q$ , is  $\frac{q}{a}$ , and the area of contact between  $q$  and the interior of the channel is  $\frac{p q}{a}$  sq. ft.

The unit frictional resistance, in pounds per square foot of water contact, is taken as  $Kv^2$ ,  $K$  being a constant and  $v$  being assumed as constant for the infinitesimal channel length,  $\frac{q}{a}$ , occupied by the quantity,  $q$ .

Hence, the total frictional resistance acting against the flow of the quantity of water,  $q$ , is  $\frac{p q}{a} Kv^2$  lb.; and the work done by  $q$  per ft. of forward movement in overcoming this resistance is  $\frac{p q}{a} Kv^2$  ft.-lb. (Criterion 2).

Equating the work done to energy consumed, Criteria (1) and (2) furnish the following:

$$\frac{p q}{a} Kv^2 = w q f \dots\dots\dots (104)$$

which, when simplified, becomes identical to Equation (1).

Since  $f$  is the head loss per linear foot of channel,  $w f$  is the energy, in foot-pounds, lost by 1 cu. ft. of water in advancing over 1 lin. ft. of channel; and, since  $Q$  = the quantity of water passing, in cubic foot per second, the rate of energy loss at any particular cross-section of the stream, in foot-pounds

per second per linear foot of channel, is  $Q w f = w a v f$  (assuming the factor,  $f$ , to cover all losses).

From Equation (1),  $w a v f = K p v^3$ . Therefore,  $K p v^3$ , or its equivalent,  $\frac{w p v^3}{C^2}$ , is the power loss per linear foot of channel.

The ratio of the power-loss rate to the kinetic power delivered is seen to be  $\frac{f}{h} = \frac{n}{m} = \frac{2g}{C^2 r}$ .

It would appear that Mr. Simham's equations are incomplete in that they take no account of the progressive changes in the hydraulic elements of the stream section.

In Equation (71) it is necessary to recognize that the quantities,  $p$  and  $v$ , represent coincident factors at one particular cross-section of the stream; that is,  $K p_x v_x^3$  is the rate of power loss at Section  $x$  and  $K p_y v_y^3$  is the rate of power loss at Section  $y$ . Hence, the total power loss between Sections  $x$  and  $y$  is,

$$\frac{K l}{2} (p_x v_x^3 + p_y v_y^3) \dots \dots \dots (105)$$

It is also apparent that the total loss of power between Sections  $x$  and  $y$  is:

$$W F = \frac{W l}{2} (f_x + f_y) \dots \dots \dots (106)$$

From Equations (105) and (106),

$$K (p_x v_x^3 + p_y v_y^3) = W (f_x + f_y) \dots \dots \dots (107)$$

This reduces to

$$p_x v_x^3 + p_y v_y^3 = Q C^2 (f_x + f_y)$$

Equation (107) is the true power-loss equation rather than Equation (71), and hence the resulting Equation (76) is, as Mr. Simham states, incomplete.

With reference to Mr. Simham's observations on the scouring of stream beds, the velocity of the water in immediate contact with the wetted perimeter is the determining factor in scouring, rather than the mean velocity; so that one of the factors affecting scouring is the degree of velocity uniformity in the cross-section of the stream. This consideration would lead to the conclusion that the mean velocity required to produce scouring of a given material depends largely on the shape of the stream section and on local conditions and circumstances.

A consideration of the general principles governing weir discharge brings up many interesting digressions, one of which is discussed by Mr. Simham under the head of "Discharges from Catchment Basins".

The writer would call attention also to Equation (39), in which,  $H_0$  is the elevation of a reservoir flow line above the crest of a spillway weir,  $Q$  is the coincident flow over the weir, and  $b$  is the net width of the stream on the weir crest.

Reservoir flow-line elevations are commonly computed from the Francis weir formula,  $Q = c b H_0^{3/2}$ , with the assumption that  $c = 3.33$ . This reduces to,

$$H_0 = 0.4484 \left( \frac{Q}{b} \right)^{2/3} \dots \dots \dots (108)$$

The coefficient in Equation (39) is seen to be considerably greater than that in Equation (108). Furthermore, Equation (39) is predicated on zero friction losses in approaching the weir, and if appreciable friction losses exist the coefficient in Equation (39) would be even greater than 0.4717.

The trouble with Equation (108) is that its coefficient is obtained experimentally from measurements of  $H$  "a short distance up stream" from the weir, where the velocity of approach is assumed as being zero but where, as a matter of fact, there is undoubtedly some surface velocity even if  $\frac{Q}{a}$  is negligibly small. The effects of these surface velocities are apparently not entirely eradicated even by the use of a stilling-box. Equation (38) would indicate that the value of  $c$  in the Francis formula, corresponding to an absolute zero velocity of approach, is 3.087.

Paper No. 1723

FOUNDATIONS AND DRAINAGE OF HIGHWAYS\*

By ALBERT C. ROSE,† Assoc. M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. HARRY TUCKER, WINSLOW H. HERSCHEL,  
CHARLES TERZAGHI, D. P. KRYNINE, AND ALBERT C. ROSE.

SYNOPSIS

This paper is based on field studies made by the writer in the Pacific Northwest during 1920 and 1921. The object of the studies was the development of simple and practical field tests and methods of identifying good, fair, and bad sub-grade soils.

As a result of the investigation the volumetric shrinkage of the soil was concluded to be the fundamental adverse factor. For measuring this, a linear shrinkage test was devised, as the displacement of pavements seemed to be caused principally by the distortion of the sub-grade in one direction—vertically. The procedure for the field moisture equivalent test was devised to prepare soils for the linear shrinkage test by wetting them with comparable quantities of water; but later it came to have a value of its own.

These tests were used on existing sub-grade soils, and the corresponding pavement conditions were observed. It was noted that an increase in the clay content of the soil, which was indicated by the test values, was accompanied by a corresponding adverse condition of the pavement.

Taken together, the field observations led to the conclusion that certain test limits could be used to identify good, fair, and bad sub-grade soils for the purpose of making a detailed sub-grade survey. A trilinear soil-classification chart, used in combination with a United States Bureau of Soils map,

\* Presented at the Spring Meeting, Asheville, N. C., April 22, 1927.

† Highway Engr., Bureau of Public Roads, U. S. Dept. of Agriculture, Washington, D. C.

further simplified the work and made possible reconnaissance sub-grade surveys without detailed tests.

The linear shrinkage and field moisture equivalent percentages were used to determine the character of the sub-grade soil as a foundation. The stability ratio was used to measure the drainage conditions.

#### INTRODUCTION

The proper design and construction of highway foundations and the methods of providing adequate drainage are research problems toward the solution of which the up-to-date highway engineer is devoting an intensive effort. The isolation of the sub-grade variable within recent years has accelerated the study of this fundamental road problem—the foundation. Intimately associated with the study of the character of the foundation is the kind of surface that is appropriate for a particular location.

The study of highway foundations and of drainage in connection with the surfaces involves two phases: (1) The economic; and (2), the engineering. The first determines the broad general policies, which establish the location of the road between controlling points; the amount of public revenues available for the work; the existing traffic requirements; a forecast of future development; the cost of operation of vehicles over various types of surfaces; and kindred subjects. The second, the engineering phase, although no less important, is more limited in its scope. It prescribes the design of grades and alignment to suit the terrain; measures the drainage requirements; plans the cross-section and surface of the road; and takes care of all the work involved in the design, construction, and maintenance of the roadway.

Only the engineering features of the problem will be discussed in this paper, and they will be limited principally to showing methods of detecting good and bad sub-grades and drainage, and to outlining the problem of designing surfaces. A careful analysis of engineering literature indicates that pavement, or surfacing, design involves four major variables: (1) The character of materials in, and the quality of workmanship on, the surfacing; (2) the local climatic conditions; (3) the character and condition of the sub-grade soil; and (4) the kind and amount of traffic. Probably at some future time these variables may be evaluated within broad limits, so that the highway engineer may be able to determine a rational surfacing design for any section of road when the local values of the variables are known.

Of the four variables mentioned, the sub-grade seems to be the most important; and in the sub-grade the volume changes caused by variations in moisture content and frost action are the factors that seem to be of greatest concern to the highway engineer. It is granted that no road surface would go to pieces without heavy traffic, but the distortion of the sub-grade due to volumetric changes must first take away the support from the surfacing before a pavement will go to pieces. As far as the other two variables are concerned, either they may be controlled, as by proper workmanship or material, or allowance may be made in a design for the known climatic conditions.

# VERTICAL DEFORMATION THE FUNDAMENTAL ADVERSE CHARACTERISTIC OF SUB-GRADE SOILS

*Analysis of the California Study.*—In a paper,\* C. A. Hogentogler, Assoc. M. Am. Soc. C. E., presents an enlightening and constructive analysis of the relative effect of various types of sub-grade soils on pavement conditions covering about 1200 miles of concrete surface in the California State Highway System in 1920. His tabulated analysis (Table 1) indicates that the undesirable conditions of the sub-grade soils increase with the clay content. On this basis, soils may be classified with regard to their influence on pavement condition.

TABLE 1.—PAVEMENTS CLASSED AS DESIRABLE OR UNDESIRABLE, USING ONLY THREE SUB-GRADE CLASSIFICATIONS.

Type of sub-grade.	PAVEMENT CONDITION.	
	Desirable percentage.	Undesirable percentage.
Sand .....	100.0	.....
Loam .....	93.0	7.0
Clay .....	79.6	20.4

These same general conclusions were advanced by the writer after making a number of field studies of sub-grade soils as to their effect on pavements in the States of Oregon and Washington during 1920 and 1921. These investigations were prosecuted with equal diligence at all seasons of the year so that the results represent the extremes as well as average conditions of the sub-grade soils as affected by climatic variations.

*Development of Field Moisture Equivalent and Linear Shrinkage Tests.*—At the time these field studies were initiated the writer discussed the problem with highway engineers and agricultural soil experts, consulted soil bibliographies and literature, and made reconnaissance surveys of existing field conditions. Based on this preliminary information the indications were that the volumetric change in the sub-grade soils was the fundamental factor causing cracking, displacement, and other unfavorable conditions of pavements. This volumetric change might be caused either by variations in the moisture content of the soil or by frost action. It was evident, therefore, that some test should be devised for measuring the comparable volumetric changes between soils varying in the size, as well as in the character, of the component grains. It was further evident that this test should measure the linear shrinkage rather than the volumetric shrinkage of the soil since the distortion of the sub-grade that caused pavement displacement acted mainly in one direction—vertically.

The standard moisture equivalent test seemed to be the most promising method for wetting the soils with comparable quantities of water prior to

\* "California Road Survey Demonstrates the Economic Possibilities of Subgrade Studies," by C. A. Hogentogler, *Public Roads*, Vol. 7, No. 12, February, 1927.

making shrinkage tests.\* It was considered probable that, in general, a force 1 000 times that of gravity would leave a surface film of water of equal thickness around all soil grains even if they varied in size and character. This would depend, of course, on whether the individual grains were porous or solid, or had glazed or roughened surfaces.

An examination of the standard centrifuge for making the moisture equivalent test showed it to be a machine designed for the laboratory and unsuitable for the general field use of the highway engineer. It was decided, therefore, to duplicate if possible, with an inexpensive but simple and practical field test, the results secured with the standard apparatus for determining the moisture equivalent.

The quantity of water absorbed by a soil due to surface tension and adhesion was compared with the water content retained by the soil against a force equivalent to 1 000 times that of gravity (the standard centrifuge force). To do this the soil was powdered to pass a 1-mm. screen and water was dropped from a burette on the sample in an iron bowl with constant stirring. When the material attained the consistency of putty, it was compacted and the water was allowed to drop on the surface as long as it was absorbed. When the absorption was complete the surface assumed a wet, shiny appearance, which indicated the critical point of the test. Fig. 1 illustrates three stages in the test.

The water content of the soil divided by the dry weight of the soil and the result multiplied by 100 gave the "field moisture equivalent". It was found that this percentage could be determined accurately for soils if it were 20, or more. Further field investigation showed that where soils gave lower values they were so coarse-grained as to drain readily, and, therefore, were practically always good sub-grade soils. Consequently, extreme accuracy for soils with a field moisture equivalent of less than 20 was not considered of practical significance.

*Comparison of Field Moisture Equivalent with Standard Moisture Equivalent.*—An analysis by least squares of the field moisture equivalents for twenty-nine soil samples, with values ranging from 20 to 41%, indicated that they were slightly closer to the standard moisture equivalent results, on portions of the same samples centrifuged in the laboratory of the U. S. Bureau of Soils, than similar laboratory tests made by the Oregon Agricultural College.† The field moisture equivalent method was used, therefore, for a comparative wetting of various soil samples before they were moulded into 1 by 1 by 10-in. bars (Fig. 2) and shrunk to determine the linear shrinkage value. This was considered to be the difference between the wet and dry length of the bars computed as a percentage of the wet length.

Check runs of these two simple and practical field tests indicated that, while they did not give identical results they gave consistent values, as close as those obtained by other routine engineering tests. It was found that a

\* The making of shrinkage tests was suggested by C. L. McKesson, M. Am. Soc. C. E., now Materials and Research Engineer of the California State Highway Commission. The writer carried on the field studies for the Bureau under Mr. McKesson's immediate direction.

† "Practical Field Tests for Subgrade Soils," by A. C. Rose. *Public Roads*, Vol. 5, No. 6, August, 1924.

general relation existed between the values of the field moisture equivalent and the linear shrinkage, and that for tentative investigations the simpler test (field moisture equivalent) was indicative of the results to be obtained by the more difficult test (linear shrinkage). For absolutely accurate work, however, the linear shrinkage was considered the critical test.

Later, it was observed that the field moisture equivalents of a large number of soils were numerically similar to the clay contents of the soil in percentage as determined by the mechanical analyses of the U. S. Bureau of Soils shown in its *Soil Survey Bulletins*.

#### COMPARISON OF PAVEMENT CONDITIONS WITH TEST VALUES

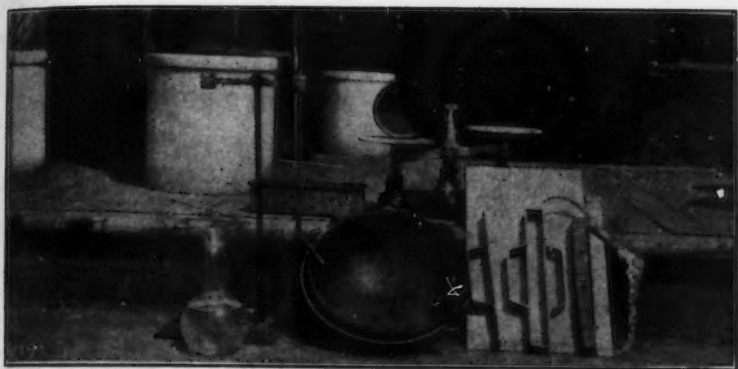

Subsequent to the development of these tests the writer made a number of field studies to determine what, if any, relation existed between the condition of the pavement and the test values of the sub-grade soil. Out of these investigations came the conclusion that the sub-grade soil was more important in its adverse effect on the pavement than the kind or amount of traffic. Pavements may crack as a result of temperature variations, but they are rarely broken up and disintegrated by traffic, except when on an unstable sub-grade or on one distorted by unequal volume changes in the sub-grade soil. Under the latter condition rigid pavements act as cantilevers or beams and are more readily broken, while non-rigid pavements become depressed, shattered, or broken through.

*Sub-Grade Failure Under a Concrete Pavement.*—One of the investigations covered the sub-grade failure under a concrete pavement, 2 miles long, between Centralia and Chehalis, Wash., laid during June, July, and August, 1914 and 1915. The severity of a part of the failure is illustrated by Figs. 3 and 4. The adverse humid climate of the region is shown by Fig. 5. During construction the average temperature was 65° Fahr. Since then the variation has been from a maximum of 99° Fahr. to a minimum of -16° Fahr., with a maximum contraction range of 81° Fahr. and a maximum expansion range of 34° Fahr.

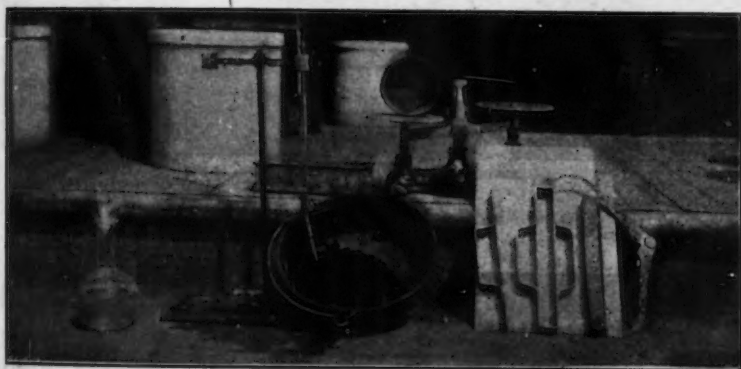

The pavement was divided into four sections based on the degree of failure in each portion. In each of these sections a 400-ft. length was selected as representative. The detailed tests were confined to these 400-ft. sections.

The investigation showed unmistakably that the degree of failure of the test sections corresponded with the increase in the values of the field moisture equivalents and linear shrinkages of the sub-grade soil. The latter are summarized in Table 2. The corresponding condition of the test sections is represented by crack charts (Fig. 6) and photographs (Figs. 7 to 10, inclusive). An adjacent section of concrete pavement laid on a sandy soil, with a linear shrinkage percentage of zero, was practically free from cracks or other defects.

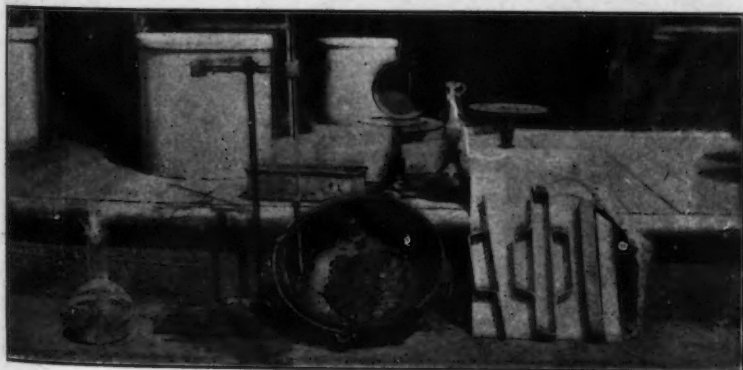

The failure of this pavement could not be attributed to defective concrete. Although tensile and compressive tests were not made, it was evident that the concrete was good. It was sound under the blow of a hammer and when broken showed a normal fracture. The construction inspector's records indicated that an adequate quantity of cement had been used for the specified mixture.

The increase in the clay content of the soil corresponded with the degree of severity of the failure even where the sub-grade varied from cut to fill, and where the fill varied in height and was overflowed annually by the flood water of the adjacent river. The mechanical analyses of the soil types, as made by the U. S. Bureau of Soils, are shown in Table 3.

The pavement failures were classified as: (1) Depressed areas (D. A.); (2) incipient failures (I. F.); (3) shattered areas (S. A.); and (4) broken through areas (B. T.). Any depression that averaged more than 0.05 ft. below a 6-ft. straight-edge was considered a depressed area. Incipient failures were depressed areas or others in which the pavement had begun to fracture but no shattering or disintegration had yet occurred. The areas were measured until the observer became sufficiently familiar with the dimensions to estimate them. An automobile speedometer was used to locate the failures along the project. A sample of the form used is shown in Table 4.

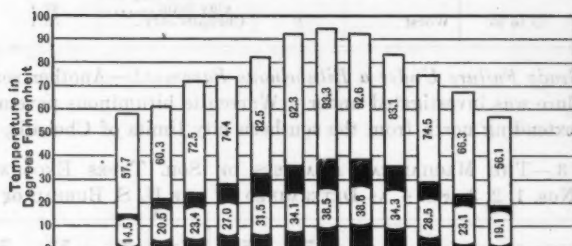

The tests of the sub-grade soil showed the field moisture equivalents to vary from 26 to 45 per cent. From previous tests,\* the corresponding linear

\* "Practical Field Tests for Subgrade Soils", by A. C. Rose, *Public Roads*, Vol. 5, No. 6, August, 1924.

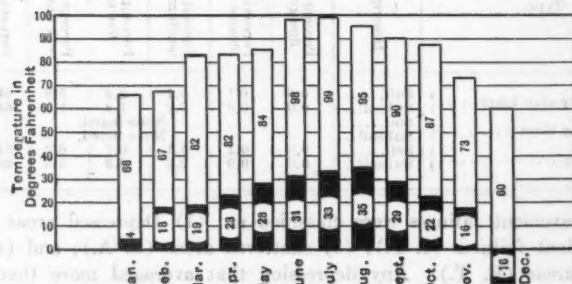

shrinkages for these moisture equivalents were estimated at 3 to 9 per cent. The soil map made by the U. S. Bureau of Soils over this area showed the predominating soil types to be members of the Salkum series. The mechanical analyses in Table 5 show the clay content to be well in excess of 30 per cent.

FIG. 5.—CLIMATOLOGICAL DATA FOR REGION IN VICINITY OF CENTRALIA AND CHEHALIS, WASH., COMPILED FROM RECORDS OF U. S. WEATHER BUREAU.

The investigation indicated that the 2-in. Warrenite wearing surface, on a 2-in. new stone course, over a 6-in. old macadam road, was not heavy enough to withstand the traffic under the existing adverse soil conditions and the inadequate surface drainage and sub-drainage. As a whole, the pavement was a failure, 34.6% of the total area being defective, distributed throughout the entire length of the pavement.

*Results of the Field Investigations in the Pacific Northwest.*—The foregoing two examples illustrate the findings of the sub-grade studies in the Pacific Northwest. As a result the linear shrinkage of the soil was considered

to be the critical test and the field moisture equivalent was taken as a simple and rapid indication of this value. The exceptions to the rule have been noted in previous papers by the writer.\*

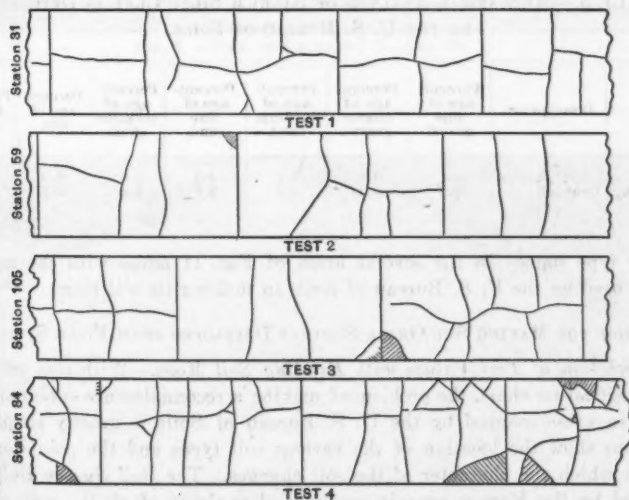

FIG. 6.—TYPICAL CONDITION CHARTS OF CONCRETE PAVEMENT AT THE SEVERAL TEST SECTIONS.

The method was further simplified for rough reconnaissance purposes by considering the clay content of the soil (expressed in percentage) as indicative of the field moisture equivalent, and, therefore, of the shrinkage value of the soil, a relation that experience had shown to be reasonably safe. The advan-

\* "Practical Field Tests for Subgrade Soils", *Public Roads*, Vol. 5, No. 6, August, 1924; "Field Methods Used for Making Subgrade Surveys," *Public Roads*, Vol. 6, No. 5, July, 1925; and "The Present Status of Subgrade Studies," *Public Roads*, Vol. 6, No. 7, September, 1925.

tage to be gained by using this relation lies in the fact that it enables the highway engineer to interpret, for purposes of sub-grade study, the great volume of data already made available by the U. S. Bureau of Soils, showing the mechanical analyses of soils of all varieties found in all sections of the country. For purposes of ready interpretation of these data a trilinear soil classification chart was developed (Fig. 11). The classification of sub-grade soils by texture is, as follows:

Soils containing less than 20% of clay:

Coarse sand—more than 25% of fine gravel and coarse sand, and less than 50% of any other grade.

Sand—more than 25% of fine gravel, coarse and medium sand, and less than 50% of fine sand.

Fine sand—more than 25% of fine sand or less than 25% of fine gravel, coarse and medium sand.

Very fine sand—more than 50% of very fine sand.

Soils containing 20 to 50% of silt and clay:

Sandy loam—more than 25% of fine gravel, coarse and medium sand.

Fine sandy loam—more than 50% of fine sand or less than 25% of fine gravel, coarse and medium sand.

Very fine sandy loam—more than 35% of very fine sand.

TABLE 5.—MECHANICAL ANALYSIS OF SALKUM SILTY CLAY AS DETERMINED BY THE U. S. BUREAU OF SOILS.

Type.	Description.	Percent- age of fine gravel.	Percent- age of coarse gravel.	Percent- age of medium sand.	Percent- age of fine sand.	Percent- age of very fine sand.	Percent- age of silt.	Percent- age of clay.
Salkum silty clay	Soil.....	0.5	1.2	1.1	3.3	3.1	59.4	31.5
	Subsoil.....	0.2	1.1	1.2	3.2	3.6	55.6	34.6

The type names in the several areas of Fig. 11 agree with the nomenclature used by the U. S. Bureau of Soils in making its soil maps.

#### METHOD FOR MAKING SUB-GRADE SURVEYS DEVELOPED FROM FIELD STUDIES

*Correlation of Test Values with Existing Soil Maps.*—With this trilinear soil classification chart, the problem of making a reconnaissance sub-grade soil survey in areas mapped by the U. S. Bureau of Soils is greatly simplified. The maps show the location of the various soil types and the points on the roads at which the character of the soil changes. The *Soil Survey Bulletins* published by the Bureau contain mechanical analyses of all the soils shown on the maps. The nomenclature of the maps and the *Bulletins* agree with that of the trilinear soil classification chart.

It becomes a simple matter then for the engineer studying sub-grade conditions to determine from the maps the type of the soil at particular locations, and, by the use of the *Bulletins* and the trilinear chart and by the employment of the observed relation between the field moisture equivalent and clay content, to distinguish between the soils that are clearly good sub-grades and

FIG. 9.—TYPICAL VIEW OF LAKE BED AT LAKESIDE.

FIG. 10.—TYPICAL VIEW OF LAKE BED AT LAKESIDE.

those that are clearly bad sub-grades. Of course, there will always be some soils of doubtful character, which it will be necessary to test either by the simplified methods described herein or by more elaborate laboratory methods; but the number of such cases is relatively small.

The field observations indicated that for the purpose of making sub-grade soil reconnaissance surveys, the clay content by mechanical analysis may be considered equal to the field moisture equivalent. When the field moisture equivalent was less than 20, the linear shrinkage percentage was usually negligible and the soil made a good sub-grade; when the field moisture equivalent varied from 20 to 30, the linear shrinkage percentage usually did not exceed 5 and the soil made a fair sub-grade; and when the field moisture equivalent exceeded 30, the linear shrinkage percentage usually was greater than 5% and the soil made a poor sub-grade.

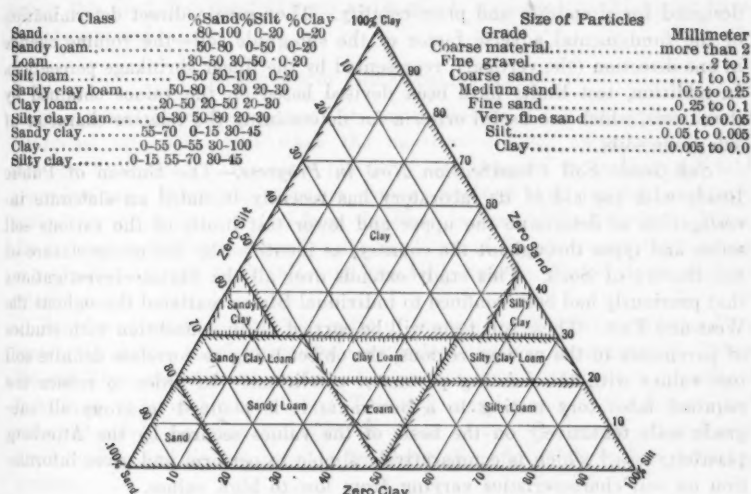

FIG. 11.—TERMINAL SOIL CLASSIFICATION CHART.

The results vary considerably in individual cases and are based on observations made in the Pacific Northwest. Before they are accepted for any other region, or for any particular project, they should be verified by actual tests.

The tests for field moisture equivalent and linear shrinkage are not claimed to indicate good, doubtful, and bad sub-grade soils under all conditions. No tests, however refined, that have yet been devised, will accomplish this. In the field studies in the Pacific Northwest certain pavement conditions could not be explained on the basis of the field test values. Although not 100% effective, the tests, however, were significant, in the great majority of cases, and it is believed that they will be of value to the field engineer until some simpler and more effective method is devised.

They were also found to be usable by a highway engineer with only moderate preliminary training. They are now being used by the State of California and have been included in those under investigation by the U. S. Bureau of Public Roads. Frank H. Eno, M. Am. Soc. C. E., in his summary of the progress of soil investigations states\* that "Rose's limits for shrinkage at 5 per cent. and moisture equivalent at 20 per cent. seem to be working out satisfactorily in practice where they have been used."

The writer believes that the results secured with the field tests developed in the Pacific Northwest and their subsequent use by other States have demonstrated their usefulness for the detection of good, doubtful, and bad sub-grade soils. The consistency of the test results has been verified in the laboratory of the U. S. Bureau of Public Roads by the close agreement between check tests made by the same investigators and between those on the same samples made by different investigators. They are advocated primarily as field tests designed for simplicity and practicability. They give a direct determination of the fundamental adverse factor of the sub-grade soil—the volume change in one direction (the vertical), represented by the linear shrinkage percentage. In addition, test limits have been devised based on the values obtained by these tests, which are useful criteria for determining the relative character of sub-grade soils.

*Sub-Grade Soil Classification Now in Progress.*—The Bureau of Public Roads with the aid of its laboratory has recently initiated an elaborate investigation to determine the upper and lower test limits of the various soil series and types throughout the country, as identified by the nomenclature of the Bureau of Soils. This study extends over all the States—investigations that previously had been confined to individual States scattered throughout the West and East. These soil tests will be carried on in connection with studies of pavements in the various regions, the object being to correlate definite soil test values with the existing pavement conditions. In order to reduce the required laboratory testing to a minimum it is planned to group all sub-grade soils tentatively on the basis of the values secured by the Atterberg plasticity test,† which is comparatively simple to perform and gives information on soil characteristics varying from low to high values.

Later, more elaborate tests will be made on representative samples of each of these groups, to determine the maximum and minimum values of such engineering characteristics as the compressibility, elasticity, and permeability. The values will be determined for each soil horizon (or depth below the surface) for each group, so that the highway engineer may know the effect of raising or lowering the grade line. By this method, in connection with correlated observations on existing road conditions, it is hoped to identify all the U. S. Bureau of Soils types and series with regard to their efficiency as sub-grade soils. Under this plan Melbourne clay might be found to fall within the doubtful group, while a Chehalis clay might always lie in the bad group.

\* "Progress in Subgrade Soil Investigations," by Frank H. Eno, Paper delivered before the Twenty-fourth Annual Convention of the Am. Roadbuilders Assoc., Chicago, Ill. January 13, 1927.

† "Simplified Soil Tests for Subgrades and Their Physical Significance," by Charles Terzaghi, M. Am. Soc. C. E., *Public Roads*, Vol. 7, No. 8, October, 1926.

Also, it might be found best to lay the grade line of the highway in the good surface horizon rather than on the bad sub-soil.

When this work is completed it is hoped that the soil series and types as mapped by the U. S. Bureau of Soils will be converted into terms that are usable for the highway engineer. The objective of all these laboratory tests and correlated investigations on road conditions will be to reduce the necessary testing to a minimum. Thus, for any given region, the soils will be classed with respect to their physical characteristics, and later, when field survey data have been received, they will be classed with regard to the physical condition of the pavements laid on them.

Until the results of these tests become available, however, and even after the work is virtually completed, there will always be a need for practical and inexpensive field tests to identify the character of the doubtful soils. It is to satisfy this need that the field tests and methods suggested in this paper have been formulated.

#### DEFINITION OF THE STABILITY RATIO

In making the shrinkage tests it was noticed that the soil could not be compacted into solid bars when the moisture content exceeded the field moisture equivalent. This same plasticity was observed in making the field auger borings. When the moisture content was less than the field moisture equivalent, the drillings issued from the earth in hard, shiny "worms". When the moisture content was excessive, the condition of the soil varied from sloppy to putty-like, to soft, to friable; and the drill could be pushed down without rotation.

For these reasons the stability ratio of the soil was defined as the moisture content divided by the field moisture equivalent (both in percentage).<sup>\*</sup> When the stability ratio of a sub-grade soil is greater than 1, the soil is considered to be in an unfavorable condition. This ratio applies only to the fine-grained soils with a field moisture equivalent in excess of 20. The coarse-grained soils drain readily and do not seem to be materially affected by a like moisture content.

The observations on well-drained soils in the Pacific Northwest in the open fields, or in highway rights of way not under a pavement surface, indicated that the maximum moisture contents of the soils were less than the field moisture equivalents. This applied to samples taken far enough beneath the surface (about 3 to 6 in.) to eliminate the effect of water standing in slight depressions or of sheets of run-off water. This condition was found to exist even in the rainy season and within 3 or 4 hours after heavy rainfalls.

On poorly drained soils, where surface depressions or restricted sub-drainage existed, the moisture content of the natural soils, at depths below the surface comparable with the well-drained soils, generally exceeded the field moisture equivalent.

In 1925, Professor F. J. Alway, of the University of Minnesota, stated that sufficient investigations had been made over the country at large to show

<sup>\*</sup> "Practical Field Tests for Subgrade Soils," by A. C. Rose, *Public Roads*, Vol. 5, No. 6, August, 1924.

that in well-drained soils the maximum moisture contents throughout the year usually were equal to or less than the moisture equivalent. It should be noted, however, that Professor Alway's statement referred to the standard moisture equivalent made against a force equivalent to 1000 times that of gravity. Although the field moisture equivalent seems to approximate the standard moisture equivalent closely, it is not made against any force except the surface tension of the water about, and the adhesion to, the soil particles. Therefore, it should not be confused with the standard laboratory test.

On observations under pavements, with few exceptions, the moisture contents of the soil at points of failure exceeded the field moisture equivalent. The converse was true for sections of pavement in good condition.

The field observations on natural soils not covered by pavements, as well as on sub-grade soils, indicate that there is a possibility by proper pavement design of controlling the moisture content in a sub-grade soil so that it will rarely exceed the field moisture equivalent.

#### SUMMARY

These studies of the engineering factors in highway foundations and drainage show definite prospects of ultimate benefit. In the future the variables may be evaluated within broad limits, so that it will be possible to determine an adequate pavement design for any section of road where these factors are known. The following conclusions may be drawn:

- 1.—The adverse character of the sub-grade soil depends primarily on the volume change caused by variations in moisture content or frost action. The main adverse action of the volume change occurs in one direction—the vertical.

- 2.—The volume changes of the soil distort the sub-grade, which displaces the pavement unevenly and subjects it to excessive localized stresses.

- 3.—The adverse character of the sub-grade soil is shown to increase with the clay content.

- 4.—The clay content and adverse character of the sub-grade soil is indicated by certain simple and practical field tests, called the field moisture equivalent and the linear shrinkage tests.

- 5.—Detailed sub-grade soil surveys may be readily made by using U. S. Bureau of Soils maps in connection with these field tests.

- 6.—A simplified and rapid method for making a reconnaissance soil survey is by the use of a U. S. Bureau of Soils map in connection with a trilinear soil classification chart, without the use of field or other tests. Generally speaking, sands, sandy loams, loams, and silty loams are considered good sub-grade soils; sandy clay loams, clay loams, silty clay loams, sandy clays, and silty clays, doubtful sub-grade soils; and clays, bad sub-grade soils.

- 7.—The drainage condition of a sub-grade soil, as well as the bearing power, is indicated as poor when the critical point—a stability ratio of one—is exceeded. The stability ratio is defined as the moisture content divided by the field moisture equivalent.

## DISCUSSION

HARRY TUCKER,\* M. Am. Soc. C. E.—A careful study of this excellent paper prompts the following comments:

- 1.—It may be taken as axiomatic that a majority of the failures of pavements—particularly the rigid pavements—are due to unstable foundations.
- 2.—The unstable condition of the foundation is due largely to the volumetric change of the sub-grade materials.
- 3.—This volumetric change of the sub-grade material is due to its moisture content.
- 4.—The equivalent moisture content of a sub-grade material—a measure of the quantity of water which it will take up—depends approximately on its clay content.

Therefore, practically, the problem of obtaining a suitable foundation for a road may be solved by (a) providing a sub-grade material which has a low clay content, less than 25% if possible; or (b) reducing the moisture content of the sub-grade material. The latter requires some form of underground drainage to lower the ground-water level to a point where it will not be injurious either as free water or as water rising through capillary attraction.

Tile and blind drains have been long recommended by highway engineers to improve the condition of the sub-base, and the practice, for certain cases, is fairly well standardized. Their use is open to two serious objections: First, their universal use in all cases where improvement of the sub-base material is necessary would mean considerable increase in the cost of a road project; and, second, they are not always effective, for even where they are utilized serious damage may result from water which enters the sub-base from the shoulders and along the edges of the pavement, before it is carried off by the underground drains. Such unfavorable conditions would prevail during a wide range of temperature after a heavy rain, snow, or thaw. For these reasons the use of underground tile and blind drains is probably limited to cases where it is necessary to lower the level of free water, and where the question of cost is not so important.

The alternate method is that suggested by Mr. Rose, namely, the use of a sub-base material with a low clay content, less than 25% if possible. If this standard is adopted, it is probable that failures of pavement due to distortion of the sub-base will be infrequent. Is this method practicable?

The method outlined by the author would seem to be the most practicable for a great many of the Southern States. It will be found that the clay content of many of the top-soil roads is 25%, or less, indicating that this material would be ideal for a sub-base. This was pointed out by C. M. Upham, M. Am. Soc. C. E., some years ago in his description of the progressive system of building highways.† In this system all highways were graded to the standard for hard surface construction, but were surfaced with top soil or sand clay. When traffic needs demanded hard surface pavements, and finances

\* Prof. of Highway Eng., North Carolina State Coll., Raleigh, N. C.

† *Engineering News-Record*, Vol. 88, p. 202.

permitted it, the top soil was used as the sub-base. In this manner a suitable sub-base material would be obtained without increasing the cost of the road to any great extent. This method requires that the ground-water level be kept at a reasonable depth below the pavement, so that it will not cause damage as "free water".

The use of top-soil material for the sub-base will help in decreasing pavement failures. Mr. Rose has indicated a number of other soils which may be used for the same purpose, and has pointed out how the survey maps of the U. S. Bureau of Soils, together with his tri-axial diagram (Fig. 11), will enable highway engineers to select a suitable material for the foundation of highways. It is thus a problem for the individual engineer to select a suitable sub-base, consistent with the type of pavement used, the traffic needs, and the cost. It is a fruitful field of research for every highway engineer.

WINSLOW H. HERSCHEL,\* Esq. (by letter).—When one has to deal with a mushy or pasty material like wet soil, to which neither the laws of hydrodynamics nor of elastic solids may be readily applied, it is fortunate when any progress whatever can be made. Mr. Rose is therefore to be congratulated that he has to some extent brought order out of chaos. On account of the complexity of the subject it is no surprise that any proposed method fails under certain circumstances. It may be of interest to consider some possible causes for these exceptions.

The author shows that the clay content is indicative of the field moisture equivalent; that this, in turn, shows the shrinkage value of the soil; and that it is the shrinkage value which is most important as a criterion for the value of soil to support pavements. He states that " \* \* \* the displacement of pavements seemed to be caused principally by the distortion of the sub-grade in one direction—vertically." While this may be admitted, the horizontal movements of the soil should not be overlooked.

In railroad work the phenomenon of subsidence is recognized as important. Material dumped on the right of way may settle out of sight and eventually re-appear at a considerable distance to the side of an embankment, as an "island" in what would be considered solid ground. Evidently, this involves horizontal flow of the soil, and such horizontal flow takes place in the sub-grade soils of many highways, even though not to such an extent, nor in such a spectacular manner. The amount of flow depends on the consistency of the soil, and it is questionable whether any test mentioned by the author, including the more elaborate tests of compressibility, elasticity, and permeability, will adequately define the consistency of the soil. Mechanical analysis and the determination of the clay content are inadequate. Clays differ in many respects, including the percentage of colloidal matter which they contain and the state of flocculation of this colloidal matter, and these factors are not without influence on the consistency of the soil.

Consistency may be defined as the property which determines the distortion-force relation. In a simple viscous liquid the rate of distortion or flow is proportional to the force or pressure which causes the flow, and the viscosity

\* Associate Physicist, U. S. Bureau of Standards, Washington, D. C.

may be expressed by a single numerical value. With a plastic material like soil, there is no such proportionality and at least two quantities are required to define the more complicated flow-pressure relation, that is, to define the consistency of a plastic material. Space does not permit a detailed explanation of the methods of measuring and expressing the consistency of plastic material,\* but for the purposes of this discussion it will be assumed that consistency depends roughly on two quantities, namely, *A*, the pressure required to start the flow; and *B*, the rate of flow after motion has begun.

If it is admitted that consistency should be considered in tests of sub-grade soils, and that it is better to measure this composite property directly rather than to infer it from other tests, then it is a question whether information is required regarding Quantities *A* and *B*, or whether one alone will give adequate, even if not complete, information.

Perhaps in the case of asphaltic surfacing for highways, and surely in the case of soil under bridge piers, where an initial distortion may be as bad as complete failure, knowledge of Quantity *A* alone is sufficient. When, however, the soils under pavements are considered, from an economic standpoint it is impracticable to make all roads as solid as bridge piers. Rather is it desirable merely that the yielding of the sub-grade soil shall be small and gradual enough so that resurfacing will be necessary only on account of wear of the road surface, and not because the lateral flow of the soil, combined with its volumetric changes, takes away the support from the surfacing so that it goes to pieces under heavy traffic.

The rule to keep water out of the foundations is as good as ever, but again from economic reasons, perfection cannot be reached, and it is desirable to spend the available money where it is most needed and will do the most good. What appears to be necessary is the determination of the consistency of sub-grade soils with various percentages of moisture, that is, curves showing the variations of Quantities *A* and *B* with the percentage of moisture for each type of soil. Then the problem becomes one of finding at what percentage of moisture a dangerously "soft" consistency occurs, and in adopting such types of design as will maintain the moisture content below this value.

CHARLES TERZAGHI,† M. A. M. Soc. C. E. (by letter).—In the history of every applied science it is possible to distinguish three successive stages. In the first stage, due to limited experience, the ultimate solution of the problems involved seems to be within easy reach and attainable within a few years. In the second, a broader knowledge of the empirical facts is acquired and the unsuspected complexity of the phenomena almost completely destroys one's confidence as to the possibility of discovering anything resembling simple relations or fairly valid laws. In the third stage, a separation is achieved between essential and unessential facts; and, instead of universally valid laws

† Prof., Technische Hochschule, Vienna, Austria.

of Nature, modest rules are established with a small but well-known range of validity.

Mr. Rose's stimulating paper essentially deals with the first stage of the sub-grade science, in which he has played the part of a pioneer. At present, this science is passing through the worst section of the second stage, and it may be interesting to review briefly the extent to which views have changed during the seven years since 1921 when Mr. Rose made his valuable field studies in the Pacific Northwest. It usually requires outsiders to discover the shortcomings in new methods of reasoning, and the outsiders were, in this case, the Russian road engineers, backed by a long and brilliant tradition in soil science. In 1924, a few years after Mr. Rose made his investigations, the Russians started to organize their own sub-grade service (Highway Research Bureau of the Central Department of Local Transport of the People's Commissariat of Ways and Communications), and tried, as a matter of course, to avail themselves of everything that others had done in this field, particularly of the American methods. They recognized at once the weakest point of past practice. Obviously, it resided in over-estimating the importance of the properties of the soil as such. They knew from experience that the same soil may behave very differently, depending on the geological, hydrographical, climatic, and topographical conditions. They knew that no soil survey can serve its purpose unless it includes a general study of the locality, the data concerning the soil proper, such as mechanical analysis, and that soil constants represented merely a part of what is needed.

In general reconnaissance work, the Russian engineers proceed from the most essential to less essential items and, according to their technique, the quality of the raw material of the soil ranks among the less essential ones. In brief, they summarily rejected what Mr. Rose presents in his paper as Point 1 of his "Summary", protesting against what they called the conception of the soil to be "a chance association of pulverized matter". This attitude may be somewhat exaggerated; yet, it contains a great deal of truth. American engineers have learned that during the last few years. Data such as those presented in Table 2 certainly looked promising at the time when they were obtained; yet, the table is followed by the statement that "the exceptions to the rule [that the linear shrinkage of the soil be the critical test for sub-grade quality] have been noted in previous papers by the writer." Since the days when these "previous papers" were published, experience has been acquired quite rapidly. The number of exceptions was found to increase alarmingly, and—imperceptibly but irresistibly—the "center of gravity" of attention shifted from the rules toward the exceptions. There are obviously many more factors which influence the behavior of the road than one could possibly suspect seven years ago, and these are by no means as easily reached as is, for instance, the linear shrinkage. To give a few examples: The reports published during the first stage of the sub-grade science simply distinguished between good, doubtful, and poor sub-grades, and the readers were delighted to be offered such a clean-cut distinction. However, a more sophisticated generation started to inquire what the terms, "good, doubtful, and poor", really mean. The answer to this question was found to be rather perplexing because experience has shown that the same

soil, from the road engineers' point of view, may be very good or very bad, depending on whether it is encountered in a cut or in a fill. In other localities, the order is reversed, inasmuch as the transportation of the soil from the cut into the fill decidedly improves its quality. Some of the worst frost troubles on New Hampshire roads were encountered on soils that should have been excellent considering that their linear shrinkage was less than 1.

Another factor, which was not yet considered in the earlier days, was the soil profile. Mr. Rose merely dealt with the older conceptions according to which the road engineer was satisfied to investigate the nature of the material serving immediately as a foundation; that is, the sub-grade. It is what one could call a two-dimensional conception of the problem. However, within the last few years, more and more attention has been paid to the fact that every natural superficial soil deposit consists of three superimposed layers, namely, the A, B, and C horizon (top-soil, subsoil, and parent material), with very different properties, and that the behavior of the road does not merely depend on the quality of the sub-grade proper, but also to a large extent on both the thickness and the properties of the layers beneath. As a consequence, the U. S. Bureau of Public Roads adopted, quite recently, the practice of combining the work of the survey party with the work of a soil scientist whose sole duty consists in exploring the soil profile and obtaining other data which are not disclosed by the laboratory test. This new policy was the inevitable outcome of the growing insight into the complex character of the sub-grade problem, and it is practically identical with what Russian engineers have done since 1925. The new policy requires the development of novel methods for expressing the results of field observations on road maps which show, not only the character of the narrow strip of land to be occupied by the road, but also the adjoining belt, together with its hydro-geological characteristics, and the stratification of the soil from the surface down to the parent material.

Similar imperceptible, but nevertheless quite revolutionary, changes have taken place within the last few years in the engineer's attitude toward the soil tests themselves—a change which is hinted at in the last part of the paper. When the first soil tests were completed, many years ago, each test represented a kind of patent medicine—its causative relations to the others being practically unknown. It was believed that a single test or two was sufficient to express, for practical purposes, the character of the sub-grade. The effects of a similar belief depreciated the value of the otherwise excellent work of the Swedish Geo-Technical Commission performed in 1914-22. Since then, however, engineers have learned that the situation is by no means so simple. Soils which, for instance, have the field moisture equivalent and the linear shrinkage in common may be very different in all their other aspects; and these other aspects may have on the quality of the sub-grade an equal or more important influence than the linear shrinkage. This behavior is particularly conspicuous with soils that represent a very poor sub-grade in spite of their low linear shrinkage, as, for instance, many of the soils in Northern New England. Hence, the efforts of investigators gradually turned from the original goal of correlating the results of one single soil test with the behavior of the roads to

a broad investigation of the manifold properties of the soils—of their physical meaning, their inter-relation, and their bearing on the results of the various soil tests. Thus, not more than a few years ago, it was still believed that the Rose test expressed essentially the same properties as does the centrifuge moisture equivalent. A more careful analysis, backed by a knowledge of the underlying physical facts, disclosed that the two tests have very little in common, in a physical sense. Attempts were made to establish a mathematical relation between the silt content and the moisture equivalent. At present, engineers know the reason why there cannot possibly exist anything but a very crude statistical relation between these two quantities, valid merely for the average of a great number of different test results, but certainly not for individual materials.

The first results of these broader investigations\* reflect, clearly, the utter complexity of the situation. They disclose the necessity of exploring the field even more thoroughly before one can dare to decide which and how many soil tests will be required for identifying soils reliably and at a minimum amount of time and labor.

These supplementary statements by no means curtail the merits of this paper. It undoubtedly has a lasting value as a lucid presentation of the early tentative efforts to solve the sub-grade problem, and of the opinions which served as guides. The test that bears Mr. Rose's name still ranks to-day among the simplified soil tests that deserve serious consideration.

D. P. KRYNINE,† M. A. M. Soc. C. E. (by letter).—The writer's intention is to treat only three specific details in Mr. Rose's paper.

*First.*—He believes that the distortion of the soil is not only vertical, but also horizontal. Inasmuch as the greatest part of the horizontal forces are counterbalanced, the visible influence of a bad sub-grade is mostly, but not always, equivalent to the action of great negative vertical forces only, such as in the case of swelling.

*Second.*—The author states that field moisture equivalent is indicative of the shrinkage value, which in turn is important for determining the value of the soil. The content of clay by mechanical analysis, according to the author, may be considered equal to the field moisture equivalent. In other words, if the sand particles in a soil are separated from the clay, and the clay content is determined, there is a criterion for judgment of the quality of the soil as sub-grade. In reality, this is not so. The mechanical analysis and the application of soil maps in connection with Feret's tri-axial diagram seem to be insufficient for the purpose.

*Third.*—The author cites the example of a 2-in. Warrenite wearing surface on a 2-in. new stone course over a 6-in. old macadam road. He states that this surface "was not heavy enough to withstand the traffic under the existing adverse soil conditions and the inadequate surface drainage and sub-drainage". The old macadam had naturally worked in the same conditions of sub-grade and drainage. Therefore, there may be two basic cases: (a) before the

\* "Present Status of Subgrade Soil Testing," by Messrs. Hogentogler, Terzaghi, and Wintermeyer, *Public Roads*, Vol. 9, No. 1, March, 1928.

† Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

construction of the Warrenite the old macadam had been in good condition, and hence the deterioration of the Warrenite is not due to the bad sub-grade; (b) before the construction of the Warrenite the old macadam had also suffered from the sub-grade distortion, in which case the question arises as to why the new Warrenite surface has been constructed over a base that was known to be in bad condition; naturally, there may be a third case (c) in which the traffic on the Warrenite has become greater than it had been on the macadam. If this is so, one may be led to the conclusion that a poor sub-grade can be tolerated unless the traffic attains a certain volume.

ALBERT C. ROSE,\* Assoc. M. Am. Soc. C. E. (by letter).—The writer desires to express his appreciation of the able discussion made by Mr. Tucker. It is gratifying to learn that Mr. Tucker's experience and that of another eminent road builder in one of the Southern States, confirm the findings of the sub-grade studies made in the Pacific Northwest.

The writer agrees with Mr. Herschel that the horizontal movement of the soil should not be overlooked. That Mr. Herschel's observation is correct is confirmed by the writer's experience in highway grading operations at the mouth of the Columbia River, in Clatsop County, Oregon, with respect particularly to tideland soil deposits. In common with the experience of other highway and railroad engineers, the writer observed that embankment slope stakes, placed at a predetermined distance before the fill was made, would be found, after the embankment was constructed, to have been thrust outward and upward for a considerable distance by the lateral and upward pressure at the toe of the slope caused by the weight of the superimposed material concentrated near the center of the fill. In many cases, this final distance between the slope stakes was found to have increased to a considerable degree beyond the measurements indicated in the original cross-sections.

The writer believes, however, that the need for the consistency test advocated by Mr. Herschel applies largely to the undrained tideland soils, in which there is a distinct flow of the wetted material, the area of which in the Coastal States is insignificant when the percentage is compared with the total area of the upland mineral soils. Because of this restricted area of the tideland soils, composed mainly of decomposed organic matter, it is believed that the consistency test is of secondary importance. In the drained tideland the lateral movement is eliminated to a considerable degree, and in the upland soils, by adequate drainage provisions, it should be possible to restrict the adverse action of the sub-grade soil principally to the vertical movement caused by the expansion or contraction brought about by alternate freezing and thawing or by variations in the moisture content; neither of which actions is considered to involve flow.

Professor Terzaghi calls attention to a statement made by the writer that, "the exceptions to the rule [that the linear shrinkage of the soil be the critical test for sub-grade quality] have been noted in previous papers by the writer". The insert in the brackets is the impression gained by Professor Terzaghi from the text. This impression, however, is erroneous, as the

\* Highway Engr., Bureau of Public Roads, U. S. Dept. of Agriculture, Washington, D. C.

context of the original paper will show. What the writer stated was not that the exceptions to the rule that the linear shrinkage of the soil was the critical test for sub-grade quality, had been noted in previous papers (although this was true in a subordinate sense), but that the field moisture equivalent was taken as a simple and rapid indication of what the linear shrinkage values would be for identical samples of soil, and that exceptions to this statement had been noted in previous papers. This relation between the linear shrinkage value and the values of the field moisture equivalent have been discussed at considerable length by the writer in previous papers.\*

The writer agrees, however, that there are exceptions to be found to the statement that the linear shrinkage value is the critical test for sub-grade quality. For example, Mr. E. R. Hoffman, formerly Construction Engineer for the Washington State Highway Department, reported that the maximum heave caused by frost under a concrete pavement in the irrigated section of Yakima County, Washington, was approximately 5 in. The sub-grade where the maximum heave occurred, was largely sand and gravel, a material in which the linear shrinkage would be negligible. The water-table, however, was in close proximity to the base of the pavement, and the frost penetration was approximately 9 in. at the edge, as compared with 15 in. at the center, of the pavement. The 5-in. heave referred to by Mr. Hoffman was specified to be the excess of the rise in the center over that at the edge of the pavement, as determined from the original crown of the surface. No spirit-levels were available, however, to determine the total heave.

Mr. Hoffman believed that the explanation of the heaving of the center of the pavement might be found in the excessive depth of the frost penetration at that location, and that this condition might be accounted for in part by the exposure of the center of the pavement when the snow blanket was removed so as to keep the road open to travel. The snow piled along the edges was considered to have been a protection against frost. Mr. Hoffman stated that there might have been other contributing causes, such as the condensation of the greatest amount of moisture under the center of the slab.

The unusual drainage conditions existing on this project, however, should preclude it from consideration as an exception to the general rule that clay soils (those with a relatively high linear shrinkage value) constitute unfavorable highway sub-grades. The testimony is overwhelming that the quality of a sub-grade may be determined largely by its clay content, as evidenced by the written experience of numerous highway engineers.

To recite the practice of actual field investigators, it is recognized that the most favorable period in which a sub-grade survey may be made is during or immediately following a heavy rain, when drainage conditions are at their worst. At this time it is generally a relatively simple matter to anticipate the location of the unfavorable sub-grade soils by their muddy condition as compared with the well-drained appearance of the more favorable sub-grades. To approximate this natural phenomenon, involving rain, the writer believes

\* "Practical Field Tests for Subgrade Soils," *Public Roads*, Vol. 5, No. 6, August, 1924; "Field Methods Used in Subgrade Surveys," *Public Roads*, Vol. 6, No. 5, July, 1925; and "The Present Status of Subgrade Studies," *Public Roads*, Vol. 6, No. 7, September, 1925.

that the simplest and most practical test consists of the addition of water to a dried sample of the soil. The field moisture equivalent seems to be the nearest approach to this natural condition, since it was discovered that it represented the maximum moisture content of a well-drained soil even immediately after a heavy rain. This statement applies to a sample taken beneath the surface so as to eliminate the effect of any ponded surface water. Because of this natural relation the field moisture equivalent was adopted as the logical basis for adding comparable quantities of water to soils, with varying sizes of grains, as a preliminary to making the linear shrinkage test—which is believed to represent the fundamental adverse characteristic of a sub-grade soil.

The writer believes that the field moisture equivalent is the simplest, most rapid, most logical, and most practical test which has yet been devised to determine the general nature of a sub-grade soil. The close agreement of test results on identical samples by different investigators has been noted as another element in its favor, because of the small degree in which it involves the personal equation of the operator.

Professor Terzaghi is misinformed when he states that the soil profile was not considered in the writer's earlier investigations. On the contrary the *Bulletins* of the U. S. Bureau of Soils, upon which the writer based his method, for many years had included soil profiles as a part of the information with regard to the various soil types. Furthermore, the original investigations made by the writer on pavement failure were carried on in compliance with a standardized questionnaire form distributed to the Field Offices by the Headquarters' Office of the U. S. Bureau of Public Roads. The instructions on these mimeographed forms required that samples of the soil be forwarded to the Washington Office; that the horizontal and vertical location of the sample be given; that it be stated whether the sample represented the material extending at least 3 ft. below the road surface; and the depth at which a more pervious or impervious layer existed beneath the material representing the sample. This necessitated considerable drilling with a hand soil auger with pipe extensions for reaching depths in excess of 6 ft. The general practice, as shown by the records on file in the Bureau, was to bore down to the impervious layer. This involved drilling, in some cases, to a depth of 20 ft. A careful statement of the character of each soil layer was noted on a soil profile plotted for the length of the test section of road.

Later, when the method for making sub-grade surveys was developed by the writer, it was recognized that soil borings were essential.\* As a general rule, however, since the top or immediate subsoil contained the greatest content of clay it was considered that the procedure could be simplified by considering these layers to represent the most adverse condition. Where actual observation, however, indicated that the lower subsoil, as shown, for example, on the side slopes of excavations, contained the largest percentage of clay, this material was used as a representative sample of the most unfavorable sub-grade soil. Where the cuts and fills did not exceed 6 ft. the

\* "Field Methods Used in Subgrade Surveys," *Public Roads*, Vol. No. 5, July, 1925.

soil profile could be found often by referring to the data contained in the *Bulletins* of the U. S. Bureau of Soils. The more recent *Bulletins* of this Bureau also give the soil profile down to the parent material.\*

An example of the boring and stratification sheets based on the data obtained in the earlier tests may be found in the report† of the sub-grade failure under a bituminous pavement on the Oregon Trail between La Grande and Hot Lake, Ore. This investigation was made in September, 1920. The borings showed the existence of a sand and gravel stratum from 4 to 8 ft. below the base of the pavement. The surface soil, up to 1½ ft. in depth, consisted of black loam—practically a gumbo—and beneath this there was a layer of white sand varying in thickness. The unfavorable subsoil, however, was found to be a quaking stratum between the white sand and the sand and gravel layers. This quaking layer was composed of greenish brown sandy clay grading into green coarser sand as the depth increased. The layer was evidently the remnant of an old bog or marsh. This conclusion was borne out by the geological formation of the Grande Ronde Valley in which the test was made. This valley is about 25 miles long by 20 miles wide, and is practically level, sloping slightly down hill from west to east at the rate of 10 ft. to the mile. The Blue Mountains enclose this triangular basin on all sides, towering to a height of 8 500 ft. above sea level. Geologists conclude that in prehistoric ages the mountains cracked, forming a tremendous fissure into which streams from the surrounding hills gradually deposited eroded material so as to fill the enormous cavity. The continual deposits through the ages finally formed the present broad level valley situated at an elevation of 2 700 ft. above sea level.

The pavement mentioned failed rapidly under the traffic of heavy trucks hauling material for the construction of an adjacent section of roadway. All the evidence indicated that the failure was caused by the vertical and lateral displacement (under concentrated loads) of the boggy, soft, and mushy intermediate layer of soil. The project illustrates conclusively the necessity of borings because, in this case, the adverse nature of the sub-grade was not apparent on the surface.

Professor Terzaghi's fine differentiation between the centrifuge moisture equivalent and the field moisture equivalent is interesting and instructive. The writer remains of the opinion, however, that for all practical purposes of testing sub-grade soil the identity of the two tests is sufficiently close so as not to affect materially conclusions based on the specified relation. This opinion is formed after considering the findings that have been made since the test was first promulgated. For example, in the three original papers in *Public Roads*, previously referred to, the writer showed that the test was applicable principally to soils with field moisture equivalent percentages varying from 20 to 30%, since these limits included the sub-grade soils of doubtful nature. For values less than 20% the soil was considered sufficiently coarse

\* "Field Methods Used in Subgrade Surveys," by A. C. Rose, *Public Roads*, Vol. 6, No. 5, July, 1925, p. 24, and Footnote 4.

† Unpublished report on file in records of the U. S. Bureau of Standards, Washington, D. C.

grained so as to provide a good sub-grade, and if the percentage exceeded 30 in any quantity the soil was believed to be unfavorable as a sub-grade.

This conclusion is confirmed first by the most recent researches of the U. S. Bureau of Public Roads. For example, a curve comparing the values determined on identical samples of a number of soils for the two moisture equivalent methods has been published.\* This curve shows that the two tests agree remarkably well between values of 15 and 35%, although there is considerable divergence from the 45° relation above 35 per cent.

The second confirmation of the writer's original statement was rendered by Professor Terzaghi in explaining the physical significance of the various highway sub-grade soil tests. In this paper† the relation between the two tests was shown by means of a pressure-voids-ratio diagram. The difference between the two values, in the typical case cited, was represented as 0.003 (in terms of voids ratio), one ordinate indicating the value 0.625 and the other, 0.622. Since the higher value represented the standard centrifuge test, the field moisture equivalent was graphically indicated to be less than 0.5% below the standard centrifuge value. It would seem, therefore, that all the evidence to date tends to confirm the identity claimed by the writer for the two tests.

In rebutting these contentions made by Professor Terzaghi, the writer does not wish to leave the impression of failing to appreciate the inestimable service that he is performing in his chosen field—the mathematical interpretation of soil physics. On the contrary, the writer believes that Professor Terzaghi's papers, concerned as they have been largely with expositions as to the limitations and scope of the various sub-grade tests, have done much to clarify what had been hitherto a hazy conception of the subject on the part of many highway engineers. The writer also agrees with Professor Terzaghi that the soil tests, in themselves alone, can never be made to indicate the quality of the sub-grade, because of the impossibility of duplicating in the laboratory the conditions that exist in the field. The writer believes, therefore, that the center of attention, concerning the whole matter of highway sub-grades—which has been focused for the most part on laboratory tests in the past few years—should now be shifted to the scientific study of sub-grade soils in the field. It would be unfortunate, indeed, were more valuable time taken up with minor objectives, when the major objective is to identify the character of various sub-grade soils, so as to place in the hands of the field engineer methods through the practice of which there may be built road surfaces best adapted to local conditions. The sub-grade investigations will then perform their greatest usefulness in pointing to ways and means of reducing the ultimate cost of construction and maintenance.

The difference of opinion expressed by Professor Krynine in the second paragraph of his discussion is caused perhaps by a misconception of the statements made by the writer. The writer asseverates his opinion that most

\* "Present Status of Subgrade Soil Testing," by C. A. Hogentogler, Charles Terzaghi, and A. M. Wintermeyer, *Public Roads*, Vol. 9, No. 1, March, 1928.

† "Simplified Soil Tests for Subgrades and Their Physical Significance," by Charles Terzaghi, *Public Roads*, Vol. 7, No. 8, October, 1926.

of the evidence published to date points to the conclusion that the adverse nature of a sub-grade soil in general increases with the clay content. That there are exceptions to this statement it is admitted. As Professor Krynine does not state the ground for his difference of opinion, the writer assumes that he takes exception to the statement from the standpoint that local conditions such as drainage, climate, and traffic, largely determine the manner in which a sub-grade soil will re-act regardless of its clay content. With this conception the writer heartily agrees; he never wished to convey any other impression. On the other hand, perhaps Professor Krynine's difference of opinion may be caused by a lack of similarity in the methods used on the two sides of the Pacific Ocean in determining the clay content.

With respect to Professor Krynine's third paragraph, his Assumption (c) is believed to represent the actual facts in the test under consideration. At the time this section of the Pacific Highway in Washington was built (in 1911), it was impossible for the authorities in control of road construction to foresee the tremendous increase in traffic which would occur within the brief space of a few years. In 1911, American roads in the Western States, as well as in other sections of the country, consisted of disconnected sections built for the most part adjacent to the larger cities and towns. The adoption of a comprehensive system of State highways in Washington, in common with many other States, was still in the argumentative stage, and it was not until 1921 that the Federal Aid System was enacted into law by the Congress of the United States.

In conclusion, the writer wishes to express the need of simplifying the sub-grade problem and the necessity for placing the subject on a plane which will make the results useful to the field engineer. He believes that the plan on which his original studies were made, has been and still is of distinct value to the field engineer as a working hypothesis on which to base the selection of the kind and design of the road surface for a given location. The outline of the operations made in carrying on these sub-grade surveys is recited here for a definite purpose, as follows:\*

*Report Form.—*

- 1.—Brief description of highway.
- 2.—Information with regard to adjacent roads:
  - (a) Location.
  - (b) Type.
  - (c) Sub-base and character of soil.
  - (d) Year built.
  - (e) Present condition.
  - (f) Summary.
- 3.—Description of this project: Type, etc.
- 4.—Topography of adjacent terrain.
- 5.—Geological structure of adjacent terrain.
- 6.—Soil types encountered:
  - (a) Data on borings.
  - (b) Results of soil analysis.

\* "Field Methods Used in Subgrade Surveys," by A. C. Rose, *Public Roads*, Vol. 6, No. 5, July, 1925.

*Report Form.—(Continued):*

- 7.—Drainage conditions.
- 8.—Climatological data.
- 9.—Traffic census.
- 10.—Recommendations:
  - (a) Drainage: Surface and sub-surface.
  - (b) Pavement design and kind of surfacing.
- 11.—Remarks.
- 12.—Photographs.

The writer believes that this outline indicates that his original investigations were not made with the idea that the soil tests alone would determine the efficiency of a sub-grade soil. On the contrary, he always recognized—and so stated—that the climate, traffic, drainage, and other local conditions should all be considered in the final selection of the surfacing. The method outlined for making a sub-grade survey was intended to be submitted as a working hypothesis that had been found successful in the Pacific Northwest. It is gratifying to learn that the findings of others have confirmed the results and that the study of sub-grade soils is rapidly assuming a growing significance as an integral part of the new science of highway engineering. In order that this new science may have a solid foundation, however, the writer believes that there is a need for the accumulation and analysis of facts, with regard to typical sub-grade conditions, on a country-wide scale.

GENERAL CONTRACT SYSTEM VERSUS SEGREGATED  
CONTRACTS\*

By WARD P. CHRISTIE,† Assoc. M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. EDWARD W. BUSH, WILLIAM T. LYLE, B. F.  
JAKOBSEN, C. C. MUHS, W. J. BARNEY, LAZARUS WHITE, L. S. STILES,  
GUSTAVE R. TUSKA, T. KENNARD THOMSON, H. M. DOUGHERTY, W. A.  
STARRETT, ROBERT RIDGWAY, R. E. BAKENHUS, WILSON T. BALLARD, AND  
WARD P. CHRISTIE.

INTRODUCTION

By laboring constantly for greater economy of design, the Civil Engineering Profession has developed an amazing fund of technical knowledge. This knowledge, applied, has made possible the structural growth of the country. Well-deserved commendation has come to the profession. However, it is possible that the very intensity of thought exerted along technical lines has paved the way for criticism, as well as for commendation. •

The thought has been expressed more or less frequently, that the Civil Engineering Profession in general is too thoroughly engaged in its technical pursuits to school itself in other necessary learning. The inference is, that the engineer usually does not become acquainted with those elementary principles of business, which any man should know, whose life work is concerned with construction. It is not presumed, of course, that the professional man should array himself with a business education, but rather that he should have a better understanding of the fundamentals of business management and the competitive forces with which he deals.

It has been stated, whether properly so or not, that many economies gained through increased technical knowledge are lost by unsound practice followed in the actual administration of construction. Some grounds for such a statement seem to have been evidenced by the many conferences of construction. For example, certain customs used in awarding and administering contracts are evidently sound and economical, while others are inherently wasteful. It

is now recognized that not only the amount of a bid, but even the actual cost of construction may be influenced greatly by general provisions and payment clauses of a contract. In fact, many factors affecting the ultimate cost of a project transcend entirely the field of design.

One of these factors, which is the subject of this paper, seems particularly important. It is the relationship that should exist between the various responsibilities of construction and the control of operations. In private corporate enterprise, this relationship is well established, but in the administrative work of construction, the issues are still debated. An effort is here made to throw some light on the subject by analyzing the two methods of contracting in current use. For want of a better name they are designated as the General and the Segregated Contract Systems.

Each of these two systems has its proponents and opponents among the business agencies of construction, and the engineer or architect should be on his guard to discern the motives of the individual or business group. Much has been written concerning them, and considerable has been enacted into codes of practice or law, but through it all apparently runs a forgetfulness of those who pay the bill.

The general contractor capable of financing and managing a project in its entirety prefers the general contract, because it creates a demand for his specific service. A sub-contractor may prefer the segregated contract because it enables him to deal directly with an owner, thus escaping certain abuses which can be practiced by an unscrupulous general contractor. Some architects or engineers may believe that their conceptions are carried out more satisfactorily by segregation, whereas others unquestionably lean toward it to escape the backfire of inadequate plans and specifications.

It is apparent that either the general contract or the segregated contract can be utilized to the specific convenience of one or another of the various agencies of construction, but as all those agencies are presumed to serve the owner, either public or private, and as the owner's money makes construction operations possible, it seems logical that his interests and not those of any individual, profession, or business group, should be the criterion for judgment. Using that conception as a premise, therefore, the following analysis of the basic features of the two systems is offered, with the hope that the conclusions drawn may at least stimulate collective thought.

Some of the points discussed pertain more directly to building work than to general engineering construction, but from them the engineer can readily draw proper analogies for his own field of operation. The subject is subdivided into the following sections:

- Definition of a General Contract,
- Definition of Segregated Contracts,
- Function of the General Contractor,
- Financial Responsibility,
- Legal Considerations,
- Delay in Completion,
- Relative Cost to Owners,
- Relative Quality, and,
- Accident Prevention.

## DEFINITION OF A GENERAL CONTRACT

*Building Construction.*—The general contract in building operations is an agreement entered into by an owner and a single construction agency whereby that agency agrees to deliver to the owner a structure fully completed in accordance with the plans and specifications of the designer. It places upon this single agency, known as a general contractor, the task of supplying by such agencies as he may select, all construction equipment, materials, labor, special services, and appliances necessary to complete the project; and, furthermore, obligates this agency to protect the owner against loss from suits, claims, liens, and other encumbrances.

The outstanding characteristic of the general contract in comparison with other types is centralized responsibility for financing, for general management, and for detailed timing of installations whereby the cost of the work and the time of completion may be controlled according to some rational and comprehensive plan.

*Engineering Construction.*—The general contract in engineering construction establishes duties and responsibilities similar to those in building work, but may cover either an entire project, or merely one of a number of similar sections into which the work is divided by reason of its magnitude. The significant feature of the general contract in engineering construction, as elsewhere, is that it places under a centralized management and co-ordinating control those operations which depend upon each other or interlock in time and place.

Obviously, some engineering projects have natural segregations of work entirely independent of each other, with respect to interlocking, which makes them suitable for separate contracts. Such projects, of course, are excluded from this analysis, as they do not conflict with the principles herein stated with respect to interlocking work.

## DEFINITION OF SEGREGATED CONTRACTS

The term, segregated contracts, is applied to the system of contracts whereby an owner enters directly into agreement with a number of independent contractors for the construction of the component parts of a project. Under this system no contractual relation exists between the independent contractors and, generally speaking, each is an agent of the owner. The function of co-ordinating their operations, or, in other words, the general management of the project, is performed by an agent of the owner.

In comparatively few cases of building work is the complete segregation of contracts carried out, as it is generally recognized that there must be some kind of central management by an agency that is financially responsible. Certain parts are awarded to concerns that usually operate as sub-contractors, and the remaining major portions are awarded to some principal contractor. This partial segregation, however, is subject to the same reasoning as the complete process, because the difference is only a matter of degree.

## FUNCTION OF THE GENERAL CONTRACTOR

When properly functioning, the general contractor finances the work during construction, performs certain parts of the work himself, and co-ordinates

the operations of all agencies engaged on the project, so that it may be constructed properly as a whole. Also, he assumes certain risks, peculiar to a business based on selling futures, and certain others, also, which arise merely from the presence of a number of different contractors operating on the same site. Assumption of these risks in reality constitutes an insurance business of the most hazardous kind, for which no commercial company would attempt the underwriting. As an owner cannot obtain commercial insurance against them, they are pooled and assumed in the service of the general contractor. Among the contingencies against which he protects the owner are: (a) Increased cost of construction; (b) delay in completion; (c) injury to workmen and the public; (d) patent infringement; (e) injury to adjacent property; (f) damage from the elements; (g) imperfect material and workmanship; (h) liens and the abuse of lien laws; (i) default on subordinate contracts; (j) unknown underground conditions; (k) demands for extortionate wages; (l) fire and theft; and (m) labor, material, and transportation shortage.

Contrary to popular conception, the principal function of the general contractor is not to erect steel, brick, or concrete, but to provide skillful centralized management for co-ordinating all the various trades, timing their installations, and synchronizing their work according to some predetermined plan. In other words, the essence of general contracting lies, not in the broking of sub-contracts or the furnishing of labor, materials, and equipment, but in the highly specialized function of management, the success of which depends on the personal skill and direction of capable executives.

Due to the great number of different trades entering into construction, particularly building work, all of which must be co-ordinated with the main skeleton and principal elements, those principal portions are usually performed by the general contractor's own forces. To carry out his commitment with certainty, he must have actual physical control of these parts. Mere legal or contractual control without physical facilities for performing almost any part of the work does not assure completion within the time or at the cost intended.

The mere broker of contracts cannot successfully perform the service of a genuine general contractor. If one branch of the work falls down, he cannot perform it himself, but must seek a new agency to perform it, which, at best, means serious delay. The same is true of engineers and architects, even if they have the experience and ability to manage a project. In some instances, engineers or architects have successfully performed this management function, although they have done so, not by reason of their technical skill and training, but in spite of it. They were good construction executives, as well as technicians, with an understanding of business management—a combination rarely found in either business or the professions. Ordinarily, the professional engineer's or architect's management of construction may reasonably be expected to succeed about as often as the contractor's execution of engineering or architectural design.

#### FINANCIAL RESPONSIBILITY

The general contract holds one single agency, a general contractor, financially responsible for the completion of a project within a given time and

at a specified amount. If either cost or time should over-run, it is the contractor's and not the owner's loss. This is not the case under segregated contracts wherein the designer performs the general management of the work. He does not presume to guarantee the cost or pay the penalty for delay, and, of course, should not be expected to do so, as his services are supposed to be professional. When an engineer or architect awards interlocking portions of a project to several contractors and himself performs the managerial duties necessary to co-ordinate their work, he is not exercising professional duties, but the duties of a business executive.

Perhaps the designer himself has not always perceived or understood the contingencies and liabilities which a segregated job places on an owner; nevertheless they are there, economically, ethically, and legally, and the owner cannot escape them. If the designer assumed these liabilities, the case would be different. He would then be acting as a broker, whose profit is justified, not only by the service performed, but by the risk of business which he has assumed. In that event he might well repaint his shingle to signify that he is a "Contracting Engineer", or a "Construction Contract Broker", for he is no longer strictly speaking a professional man.

The liabilities here mentioned are not theoretical or imaginary, and, in many cases, have ultimately cost the owner enormous sums. Independent contractors operating each according to his own convenience cannot avoid interference with one another. The work of each depends to a great extent upon the performance of another, and friction between the different superintendents is almost inevitable. Issues arise over the use of hoists, the laying out of conduits, storage of materials, the installation of safety devices, and other matters. Such conditions result in confusion on the job, mutual interference among the independent contractors, injection of extra expense, and the filing of perfectly legitimate claims against each other or the owner. The owner generally cannot escape payment of such claims against him, because his own representatives are named as being responsible, and because there is no financially responsible agency between himself and the independent contractors to absorb the loss.

From the owner's viewpoint, however, the broker is a "safer bet" than the professional engineer or architect; for he guarantees the price, usually has business experience, and, in the last analysis, must pay the cost of his own mistakes. When the designer splits up the work among a group of independent contractors he is acting as a broker with all a broker's financial safeguards and guaranties removed. This aspect of segregated contracts, although apparently not recognized by some professional men who have favored them on occasion, is a most vital consideration with respect to the interest of a construction owner.

If the professional man desires to engage in business, he has of course a perfect right to do so, and doubtless should do so if his capabilities lie in that direction; but to exercise the business function involved in segregated contracts, and to let an owner proceed in such cases without informing him of his liabilities, does not have the earmarks of fair play.

## LEGAL CONSIDERATIONS

To a certain extent each contractor holding an independent contract with an owner is his agent. Consequently, if one interferes with another's operations or injures him, the owner may find that he must stand suit jointly with the offending contractor. Even if the offender's agreement provides that he shall protect the owner against loss from actions brought by other contractors, such an agreement may not actually insure the protection. Obligations and responsibilities devolving upon each of the several contractors on a specific project, are difficult to determine, and the offending contractor can usually manage to shift the responsibility for injury to the owner's own representative. Moreover, the true obligations and equities of the various agencies of construction are so confused in the minds of American Courts, that there is little hope of pinning liability where it belongs. This condition is evidenced in part by the steady trend of construction toward the settlement of disputes by arbitrators familiar with the industry.

In addition to damage suits, there is also the question of criminal liability in event of accident or disaster. Rarely, if ever, has a Criminal Court in the United States convicted a contractor, designer, or owner, whose criminal negligence or wilfully dishonest actions have resulted in death to third parties. Under segregated contracts, a lack of clearly defined responsibility between the designing and construction agencies, and failure to pin these responsibilities where they belong, have made it nearly impossible to convict a guilty party. The injurious effect of such a condition upon the integrity of the entire industry must be obvious.

If an owner is sued when segregated contracts are used, he is very likely to be doubtful whether he should stand suit with the offending contractor, or join with the plaintiff against him. A properly drawn general contract, however, centralizes all responsibility in a single agency whose obligations are relatively clear. That agency can be reached at law and held responsible by an owner should the performance be upset by ignorance, negligence, or dishonesty of any agency on the work. In other words, the mere splitting up of interlocking work among a group of independent contractors, under the supervision of the owner's own representative, may place him in an extremely unsafe legal position.

## DELAY IN COMPLETION

Completion of a construction project within the time set is nearly always an important consideration to the owner, and, in many cases, is a vital one. Owners are not particularly interested in collecting penalties, but in obtaining their projects when expected. If the various operations are not "time-scheduled" in advance and constantly synchronized on the job, delay is inevitable.

All other factors being equal, it seems almost axiomatic that responsibility and control when vested in a qualified general contractor, whose own money is at stake, will insure timely completion more certainly than when vested in the owner's professional adviser. Without an existing organization trained for the work, and without equipment or other facilities for actually

taking over some backward portion, the latter is practically helpless to control the time of completion.

The points here mentioned are generally recognized by engineers and architects, but there is another point that is quite commonly overlooked, namely, delays which constantly menace construction operations in and around cities by reason of difficulties with labor. The complications of union and non-union labor, as well as open and closed shop conditions, may readily paralyze the separate contract job. No one cause is more fruitful of delay and increased cost than this, particularly when contractors from different localities are engaged on the same project. Instances are not uncommon of a project having been delayed for weeks, because one of the independent contractors on an open shop job is obliged to employ only union labor. This condition needs little comment.

Ramifications of labor problems are not confined to single companies, single communities, or single crafts. A strike on one job may be called for causes arising on some job in a distant part of the country. The labor problems of construction, like mechanical installations, require special skill and experience. They require proper contact between the employers in the various trades, functioning of their trade associations, conferences with labor representatives, sometimes an organized resistance, and, in fact, a continuous working together of all elements aside from their contact on the work. The handling of labor has become probably the most difficult phase of the construction business in many localities, and the professional man is not in a position to handle the situation.

#### RELATIVE COST TO OWNERS

Various proponents of segregated contracts have commonly sought their adoption by citing specific cases wherein the total of separate proposals on a construction project was less than the proposal for a general contract. This, they claim, demonstrates the economy of the system, but, at the same time, they fail to state that there are far more cases wherein the general contract bid is lowest. Also, there is another angle to proposal prices, which overshadows initial comparison, as follows: Assuming for the sake of analysis that plans and specifications are correct and complete, then, under a general contract, the contract price is all that the owner is required to pay; but when several independent contractors are engaged on interlocking work under the direction of an architect or an engineer, the sum of their prices rarely, if ever, constitutes the total cost to the owner. The extra expenses, as already suggested, arise from delays, interference, misplaced work, and lack of co-operation between the independent contractors. Under a general contract this over-run, if present, is absorbed by the general contractor. Under segregated contracts, it can fall only upon the owner.

In addition to the concealed expense of segregated jobs, there is also to be considered their effect upon competition. In receiving proposals for a general contract the owner obtains a double competition: First, the competition of sub-contractors dealing with general contractors; and, second, competition between general contractors. Frequently, it occurs that the general contractor,

considering a proposal for some part of the work too high, substitutes his own figures, and brings the cost within them. It is commonly recognized that he usually receives lower bids from the various trades than an owner dealing directly. He has his regular contacts with sub-contractors who wish to deal with him in the future, whereas the owners may never employ them again.

A great many of the most experienced general contractors do not bid on projects likely to be segregated, because they feel that efficient performance of their work in such event is practically impossible. The award of a single integral part to some non-co-operative individual, disrupts and increases the cost of their work. Thus, the owner loses valuable competition which would often bring in more satisfactory proposals.

Some members of the mechanical trades in seeking to establish segregated contracts have represented that general contractors add a margin to the sub-bids, for which no service is given, and that this margin—called profit—can be saved by dealing directly with sub-contractors. Some owners may not detect the fallacy of the statement, but the analytical mind of a professional man should expose it. Entirely aside from the management service of the general contractor, there are many other expenses on the work which this so-called profit must defray.

Inquiry among representative construction companies shows that the usual margin added to sub-contracts is about 5 per cent. This amount, although in some cases it may contain an element of profit, is in reality a service charge, to compensate for such items as superintendent, night watchman, hoisting, storage space, protection from weather, temporary heating, safety work, and other overhead expenses which are not included in the sub-contractor's bid. When it is recalled that the architect in private practice charges about 3 or 4% for handling sub-contracts direct, yet provides none of these things except superintendence, it is obvious that the 5% contains no great amount of profit.

Under partial segregation, the principal contractor knows that he will be required to furnish these items and, therefore, includes them in his estimate. Then, when the designer adds to this his 3 or 4% for supervising separate work, the owner pays almost a double charge for general supervision. All the independent contractors, if they have had previous experience with segregated contracts, are very likely to include some allowance for the contingencies of a poorly co-ordinated job. Income tax reports show that the average net profits in contracting have been less than 2%, and that approximately 20% of the companies made no profit in 1924; therefore, there is evidently some room for doubt about the saving of this profit under separate contracts.

The subject of cost under the two systems may be analyzed and debated endlessly, because opportunity is never afforded for a true comparison on identical projects under identical conditions. If, however, experience in other lines of business counts for anything, and if the common axiomatic principles of business management and economics are founded on fact, segregated contracts cannot avoid certain inherent inefficiencies and expenses which are eliminated by the general contract system.

## RELATIVE QUALITY

Workmanship and materials under the general contract system receive a double inspection; one by the engineer or architect to protect the owner and another by the general contractor to protect himself—for he is responsible to the owner for the work of sub-contractors. The supervising agency evidently values this latter inspection, as it is required by a great majority of contracts.

Under separate contracts, the engineer or architect can doubtless secure a satisfactory quality in the work of a specific contractor, but quality in the specific trade does not insure quality in the project as a whole. Unless the various parts have been properly timed, joined, and finished as a whole, the value of the project is impaired.

A well-known architect has stated, with respect to buildings, that there never had been, and probably never would be, prepared a complete and perfect set of plans. Some adjustment, alteration, and modification in the field is necessary. Doubtless, the same is true of engineering plans. This condition seems to necessitate some central agency in the contract to produce a structure that is integrally sound.

Proper timing of operations is a necessity on which the quality of a building project particularly depends. Conduits must be placed, not when the plumber or the electrician feels like doing so, but when forms and structural parts are ready to receive them. The heating plant is essential to the drying of walls and the execution of certain other work. Plaster, marble, tile, and painting are also dependent on the heating plant and, if it is not installed at the proper time, the results are not satisfactory.

Under complete segregation, proper joining and finish, or cutting and patching as it is commonly called, is extremely difficult to produce. Each trade seems to consider itself at liberty to bore holes, but feels no responsibility for their filling and finish. Under partial segregation, where some principal contractor is held responsible for such work, this is also a problem, as such contractor lacks control over those who cut the structure. A number of construction companies that have been consulted declared that they would like to be rid of responsibility for the mechanical trades, were it not for the fact that, when those trades operate under independent contracts, efficient operation and satisfactory conduct of the work as a whole is impossible.

## ACCIDENT PREVENTION

Owners may not know it, but they are the ones who pay the costs of accidents in construction. The cost of injuries and deaths finally finds its way back to them through high production costs, increased premium rates, and general inefficiency in construction. Safety work is, therefore, not only a humanitarian obligation, but an economic necessity. It can only be carried on successfully when centrally supervised and enforced throughout a project.

When several independent contractors are operating on the same site, intelligent, co-ordinated safety measures are neglected, and the rate of accidents increases. Responsible contractors have stated that proper safety measures are practically impossible without some centralized management on the job, whereby some one answerable for his mistakes can, if necessary, force the installation of safety measures.

In some States, failure to comply with existing safety regulations precludes protection under the Workmen's Compensation Act. The contractor and the owner in case of accident may be jointly sued for twice or triple the limitations of the Act. If the contractor sued is responsible and is acting in the capacity of general contractor, the owner is safe. No doubt exists concerning who is responsible for all parts of the work; but if there are a number of independent contractors, responsibility may not be located or placed, and the owner may be obliged to pay the damage.

#### CONCLUSION

As previously mentioned, individuals in one or another group participating in construction prefer one or the other system of contracting. The reasons of some are unselfish, whereas those of others are distinctly selfish. No group is entirely one way or the other, and, in each, there is a tendency to blame the deficiencies of human beings on a system of contracting.

When the sub-contractor seeks to establish segregated contracts because an unprincipled general contractor tries to drive his bid down to that of an irresponsible competitor, he should realize that dealing directly with an owner is not a remedy. Owners or their representatives commonly do the same to general contractors, or for trifling causes hold up large sums of his money. They will do likewise to the sub-contractor. A number of representative sub-contractors have stated that they prefer the general contract, when the owner employs a responsible general contractor.

The professional man who represents that an owner can profit by eliminating a general contractor on the grounds that he performs no necessary service, is at best uninformed. Construction service is composed of certain elements which represent relatively certain expenses. They may be re-arranged among various agencies, but they cannot be eliminated. The significant point to be considered is, which of these agencies can perform the various services most efficiently and most satisfactorily to an owner. No one presumes that a man trained to the contracting business can step into design and render proper service. Neither can the designer step into general contracting, without actual contracting experience, and perform proper management service for an owner.

The general contract system was not suddenly conceived and launched on the populace, but grew to meet the requirements of owners, through a long period of years. It has endured in the hands of individuals who were unorganized, when all industry around them had developed powerful trade associations. By its endurance has been demonstrated the soundness and economy of centralized construction management, and it should not be cast aside merely to suit the convenience of a specific trade or profession.

Rather than attempt to correct any group or individual annoyances by scrapping a system which is both theoretically sound and practical, the responsible elements of each group should co-operate in correcting abuses, particularly as those abuses will prevail under any system, until all elements concerned with construction wage war on ignorance and unethical practice within their ranks.

## DISCUSSION

EDWARD W. BUSH,\* M. Am. Soc. C. E. (by letter).—The author very admirably presents a subject which can well be studied at this time by engineers, architects, and others in charge of the letting of contracts, because, during recent years, there have been organized campaigns in certain localities to require contracts for public buildings to be let by the segregated method. Many reputable sub-contractors doing plumbing, heating, roofing, electrical work, etc., have claimed that they frequently do not get fair prices for their parts of the work because, after the general contractor is awarded the job, he makes the sub-contractors come down to the figures presented to him by, perhaps, a group of irresponsibles. Such practice is deplorable and against the best interests of the construction industry considered from the point of view of the owner, the engineer, or the architect, or the contractors interested. On the other hand, trying to cure this evil by letting segregated contracts is substituting a worse practice for one not as bad.

Other methods can and should be used to correct these bad practices. Even where a general contractor does pinch the sub-contractors a little, the owner still has the general contractor's contractual obligations standing between him and any loss or damage caused by a sub-contractor not doing his part. The right kind of a general contractor will select the right kind of sub-contractors and very often they have worked together for years and each knows just how he fits into the other's organization. This makes for economy, which is reflected in the price paid by the owner as well as the profits obtained by each contractor. No engineer or architect can fit a sub-contractor into a general contractor's organization as well as the latter, and the work will suffer, as explained so well by the author, unless there is a centralized authority and responsibility. The owner has the best chance to obtain the maximum value for the money expended if he gives a building contract to one bidder after competitive bidding. This is the time-tested method under which so much work has been and will be performed.

It is known by the writer that most of the high-grade general contractors doing building work possess the requisite knowledge to estimate closely the cost of the portions of the work which will be done by sub-contractors and such cost estimates are actually prepared as a check on the sub-contractor's bids. Unless the engineers and architects have an estimating ability equal to that of the general contractors, the owner's interests are not conserved by segregated contracts.

Referring to the 5% mentioned by the author as being added by the general contractor to the bid of the sub-contractor, it is of interest to compare this to the 5% fee very generally allowed receivers and administrators of estates on all monies coming in and going out, and these receivers and administrators are also allowed expenses and the employment of expert services if such are needed. It requires a high degree of technical ability and

\* Engr., Aetna Casualty & Surety Co., Hartford, Conn.

much tact to keep the sub-contractors of a large building job up to the mark on progress and quality of work, and if the services rendered by the general contractor were compensated for in proportion to their true value, as compared with the value often allowed by law for the services rendered by receivers or administrators, the contractor could add, not 5% to the sub-contractor's bids, but 20 to 50 per cent. The small fee actually charged by the general contractor is gross and from it must come the overhead expenses, so his fee really nets him a very small amount of profit, if any. For this fee the general contractor must assume full responsibility on the work performed by the sub-contractors. The owner must necessarily pay some one to exercise the authority needed to correlate the efforts of several organizations, and it is to his advantage to place this authority squarely on the general contractor rather than attempt by segregated contracts to save a little and make the engineer or architect carry the authority without indemnification to the owner should anything go wrong.

Even if the general contractor does add 5% to the bids of sub-contractors when making up his bid, he may not add very much more than this to the cost estimate of the part of the work to be done with his own payroll. It is the net profit he will take from the entire job which interests the owner rather than what precise percentage is added to the estimated cost of the various parts. The author has explained that building construction work is generally taken on a small margin of net profit. The writer, after reviewing a large number of contractor's financial statements, confirms this opinion.

A few years ago the contractors bidding on a large school were instructed to file separate bids for all or some of the parts, such as the main structure, the plumbing, the heating, the plastering, etc. They were told that the entire work would be let to one general contractor at an amount determined by adding the lowest bids received on the component parts; and if the general contractor did not choose to award sub-contracts to those who put in the lowest figures, these figures, nevertheless, governed the price the general contractor would receive for these parts of the work. It is difficult to imagine a more vicious form of a letting as it would place full responsibility on the general contractor and, at the same time, take from him the right to select the sub-contractors whose work he guaranteed.

WILLIAM T. LYLE,\* M. Am. Soc. C. E. (by letter).—The writer believes it to be unwise for an engineer to take the attitude of proponent or opponent of either contract system. Each has its advantages and each, its disadvantages. The author, who favors general contracts, states that "some engineering projects have natural segregations of work entirely independent of each other, with respect to interlocking, which makes them suitable for separate contracts". With this unquestionable statement, he dismisses segregated contracts from his analysis and proceeds to establish the merits of the general system.

The author establishes a good case for general contracts in building construction, basing his argument on the interlocking character of the work; but

\* Prof. of Civ. Eng., Washington and Lee Univ., Lexington, Va.

the question will arise as to when and to what extent the elements of a construction job are interlocking. In analyzing this question three considerations arise: First, the parts of the work may be so far removed in space and relationship as to be suitable for segregated contracts, as the author thinks proper; second, they may be so closely related as to constitute an organic whole for which the general contract only is suitable; and, third, they may lie between these extremes, either toward the former or toward the latter. The engineer in charge must make the decision.

It is natural for an engineer to favor the general type of contract. The writer has usually preferred it for the simple reason that responsibility for the timing of the work, legal responsibility, accident prevention, etc., is removed to a considerable degree from his shoulders and placed on those of the general contractor. In company with many of his fellow practitioners, he may have sometimes erred in this preference. The personal convenience of the engineer may not be for the best interests of the owner.

In discussing this question the professional and business equipment of the engineer must be considered. There was a time when, as a mere technician, he was poorly equipped to act as executive, but that time is passing. The modern engineer is taking to himself functions of the promoter and executive and thereby fitting himself for many kinds of important work for which he was formerly poorly qualified. He is becoming more and more a man of affairs. This change in the make-up of the practical engineer is reflected in the professional schools wherever increasing emphasis is placed on the preparation of a humanistic, economic, and administrative character.

The writer does not favor the categorical "no" of this paper. There are many large jobs, and smaller ones too, interlocking to a certain degree, and yet so spaced or spread out as to be adaptable to the segregated contract. The engineer in charge of such contracts will have more responsibility but, at the same time, can render greater service. By letting separate contracts, small contractors will have a chance to deal with the owner direct and a double profit may be eliminated. At any rate the work performed will probably be of a better quality. It is often true that the small contractor prefers to deal with the owner direct rather than with a general contractor of whose business character he is suspicious.

The writer is not undertaking to state any "yes" or "no" in the matter, but merely to emphasize the importance of weighing the pros and cons, in cost, security, and promptness of execution. He believes that both systems are useful.

B. F. JAKOBSEN,\* M. Am. Soc. C. E. (by letter).—The author somewhat forcibly emphasizes the advantages of the general contract system, as a system. The writer's experience leads him to believe that the important element is the ability and experience of the particular general contractor as against the particular construction engineer. The general contractor assumes certain risks

\* Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

and responsibilities, but the owner pays for these in any case, and it is part of the construction engineer's duties to see that these things are properly arranged.

The author admits that in some cases engineers have performed management functions successfully, not by reason of their technical skill and training, but in spite of it. It is difficult to understand this statement, and it is not clear just what the author intends to include in his expression, "technical skill and training". Of two men, one of whom has technical training and the other has not, but who are otherwise equal, there can be no doubt about which one is the more desirable. Some of the most successful contractors the writer knows are technical graduates, and this training does not seem to have affected adversely their ability to understand the management business.

In fact, it would seem self-evident that the executive who understands the reasons for the design, would be *prima facie* better qualified to carry it out. It is quite true that it is pitiful to see a theoretically competent man dabble with practical problems with which he has no experience; but it is still more pitiful to see the practical man dabble with self-conceived theories and insist that designs must be changed to accord with these strange notions of his. The latter case is of much greater frequency than the former, and when the purely practical man has gotten some theoretical conception in his head, based upon his many years of experience, he is generally not amenable to reason. On the other hand the manager of construction who has a fair understanding of the theories involved in the design, as well as of the factors influencing construction, is often in a position to assist the designer materially and thus affect a saving without other adverse effects.

The danger of over-emphasizing the advantage of the general contractor is that undue weight is likely to be given to the financial details at the expense of realities. Good accounting is valuable, but the accountant must always understand that his work is after all of a secondary nature. Many, if not all, of the larger engineering corporations which claim to be management experts are intrinsically financial experts rather than construction managers. Judging from such work as the writer has seen, neither the quality nor the cost of their work has been such as would lead any one to give their system any decided preference.

When the Constitution of the United States was being formulated, Madison insisted that this was to be a Government of laws, not of men. That may be true in a narrow sense and by comparison, but after all it is men who decide what the laws mean in each particular case, and that is what counts; or, as Pope said,

"For forms of Government let fools contest,  
Whate'er is best administer'd is best."

It is quite the same in the construction field; at best a system can make up for very little compared to the ability and skill of the individual in charge. The owner needs to look for the best man rather than for the best system.

C. C. MUHS,\* M. Am. Soc. C. E. (by letter).—Contrary to the author's opinion, the number of contractors with technical training is legion. His statements that:

"\* \* \* many factors affecting the ultimate cost of a project transcend entirely the field of design." \* \* \* "In some instances, engineers or architects have successfully performed this management function \* \* \* not by reason of their technical skill and training, but in spite of it." \* \* \* "When an engineer or architect awards interlocking portions of a project to several contractors \* \* \*, he is not exercising professional duties, but the duties of a business executive."

show a bias that is, fortunately, rarely held by a contractor with technical training and somewhat infrequently by the "practical" contractor.

In the early history of construction work, plans, in the sense of drawings, were few and sketchy, and the architect (master builder) or engineer (one who devises and controls) was practically the general foreman on the job and controlled in detail the processes used and the manner of their execution. During that epoch there was little segregation of the crafts, and even later when a contract was "letten" to John Doe, carpenter, to build a certain bridge, it was not assumed, therefore, that he knew more about building bridges than the man who designed them, but merely that by this device less detail supervision would be required by the engineer. At present, in Continental Europe, Asia, South America—in fact, practically all over the globe except North America—all engineers and architects are contractors, in the sense used by Mr. Christie, and all contractors are either engineers or architects. In view of this fact, Mr. Christie's statement that "he [the designer] might well repaint his shingle to signify that he is a \* \* \* 'Construction Contract Broker', for he is no longer strictly speaking a professional man", loses its significance.

The problem then "boils down" to a matter of expediency, because engineers are not inclined to cavil about contractors having encroached upon their field of management.

As to things affecting expediency, which Mr. Christie denominates the owner's interest, the author believes that some architects or engineers "unquestionably lean toward it [segregation] to escape the backfire of inadequate plans and specifications." The writer believes that those guilty of such omissions lean to the general contract as more likely to cover up their sins. Both practices, of course, are based on a fallacy, because the owner pays either directly or indirectly.

It is admitted that "mere legal or contractual control without physical facilities for performing almost any part of the work does not assure completion within the time or at the cost intended", but since no general contractor in building work performs more than a few of the many details involved he is not in much better case in this respect than the engineer or the architect.

The writer takes issue with the statement ending, "\* \* \* because a broker does not customarily offer effective guaranties".

\* (Muhs & Co.), Chicago, Ill.

Further, the author states, " \* \* \* to let an owner proceed in such cases without informing him of his liabilities, does not have the earmarks of fair play". If such practice exists, this statement would be a serious indictment. A considerable experience has failed to show that it is at all frequent.

There is a fallacy in the statement that, "the true obligations and equities of the various agencies of construction are so confused in the minds of American Courts that there is little hope of pinning liability where it belongs".

The owner's liability to sub-contractors and the public is only slightly affected by the existence of a general contract, his security in that case being the reliability of the general contractor—not the contractor's existence; and there are also reliable sub-contractors.

Furthermore, the writer questions the logic of the following statements: (a) "If the various operations are not 'time-scheduled' in advance and constantly synchronized on the job, delay is inevitable"; (b) "Without an existing organization trained for the work, \* \* \* the latter [the adviser] is practically helpless to control the time of completion"; (c) "The complications of \* \* \* labor \* \* \* may readily paralyze the separate contract job"; (d) " \* \* \* cutting and patching \* \* \* is extremely difficult to produce"; and, (e) " \* \* \* safety measures are practically impossible without some centralized management \* \* \*."

These are the functions that an engineer performs as an agent of the owner, and, with the exception of patching, he can perform them as well, inherently, as the contractor.

To state that "the professional man is not in a position to handle the situation", is merely to express an opinion.

As to the general contract case, Mr. Christie states:

" \* \* \* The essence of general contracting lies \* \* \* in the highly specialized function of management, the success of which depends on the personal skill and direction of capable executives."

This is wholly true, but since most of the superintendents, estimators, and contract men who have become executives in this sense are employees of technical talent, and, since such talent may be just as readily employed by the practicing engineer, it makes, not a case for general contracting as a whole, but for each individual concern.

The following statements appear in the paper:

"Assuming for the sake of analysis that plans and specifications are correct and complete, then, under a general contract, the contract price is all that the owner is required to pay; \* \* \* over-run, if present, is absorbed by the general contractor."

This is only partly true, because the greater part of such excess is extra work or "unforeseen delays", which will be charged to the owner in any case.

Certainly, "he [the contractor] has his regular contacts with sub-contractors", but so has the engineer.

It is probably true that "this amount [5%] \* \* \* is in reality a service charge". However, the inference that it includes such items as

superintendent, watchman, protection, temporary heat, etc., is wrong, as all engineers, architects, and contractors know. Hence, of this 5% a greater part is profit than would at first appear.

If the fact that income tax reports indicate only a 2% average profit for contractors means anything exceptional, it means that contractors are not handling their work well. This, the writer doubts. The same conservative source of information forces the gloomy conclusion that "nobody never made no money nohow".

Many of Mr. Christie's observations are true, but many others contain grossly exaggerated and unfair inferences, as when he states: "Conduits must be placed, not when the plumber or the electrician feels like doing so, but when forms and structural parts are ready to receive them". The inference that, under the control of an engineer or architect, the project would run "hogwild" is so often repeated throughout the paper that it should not go unchallenged. The plaint amounts to this, that engineers, by a system of segregating contracts, are usurping the functions and encroaching upon the field of the general contractor. This is measurably true, but it is not entirely true. Under such conditions engineers would be usurping the functions of the general contractor as defined fifty years ago which he, in turn, usurped from the engineer a hundred years ago. There is ample field for the general contractor without his embarking on a campaign of belittling the ability and integrity of engineers to whom he owes at least as much as they owe him.

W. J. BARNEY,\* M. AM. SOC. C. E.—Although connected with a building organization, the speaker would like to discuss this subject from the standpoint of an engineer. There is no question that, after reading this paper, engineers and contractors will realize that there is little economic, and little administrative, justification—taking the broad picture as a whole—for attempting to break up a general contract into a number of separate contracts. On the other hand, this problem has been discussed because it exists, and since it exists there must be some causes.

The speaker believes that the practice of segregating and letting separate contracts on building operations has arisen largely through a weakness in the Engineering Profession. This does not apply to a great many engineers; but there are a number in the profession to-day, particularly in the building industry, who are selling their services, not as engineers, not as technical advisers, not as men who can lay out a plant for a better operation, but purely and simply as a type of super-purchasing agent.

The speaker has known cases where engineers have said:

"You give me the commission to build this building—not because I can lay out a plan so that you will have the best building for your money; not because I can design a more beautiful building; but because I can buy this building cheaper for you than you can buy it for yourself, or because I can buy it cheaper than my fellow engineers; I am the super-purchasing engineer."

A man selling on that basis grasps at straws to help him bolster up his argument. The factory owner says: "How can you buy this building cheaper?" And the engineer replies:

\* Pres., Barney-Ahlens Constr. Corporation, New York, N. Y.

"I can buy the building cheaper because I am familiar with sub-contracts. I can save the general contractor's profits; you can eliminate the general contractor. For my fee I will furnish you the plans and specifications. I will do all the buying and I will let the contracts separately and there will be none of this large, wasteful general contractor's profits in this enterprise."

Often the factory executive accepts this type of argument; and, consequently, the Engineering Profession to-day is losing its stability and professional character because of the introduction of this element of purchasing agent.

As to this question of the segregation of contracts, it will work itself out in the long run. If it has an economic justification, the speaker will cease to exist as a general contractor and will become a sub-contractor on the concrete skeleton. However, there is something foreboding to the Engineering Profession in this tendency, which, as a member of the Society, and as one who has been an engineer, the speaker dreads to consider. The profession should stop selling itself as a purchasing agent and go back to selling itself as a technical adviser.

Look at the subject from the standpoint of facts. Suppose that an engineer has sold the owner on the basis that he can do the work cheaper. What are the facts in the case? He sends out and gets bids on the electrical work, on the plumbing work, and on the elevator work; and he says to the general contractor: "I have no objection to your doing the same thing, and we will see if you can buy as cheaply as I can."

On a preliminary estimate no sub-contractor to-day practically ever gives his lowest price, because he has been trained in the hard school of experience, and he knows that when the contract is closed and the buying begins he is going to be asked to reduce his price somewhat, perhaps to justify the existence of a purchasing agent, and perhaps also to justify the idea that the engineer is a clever fellow who can always take a few dollars off. Therefore, the engineer is asking for a price and the contractor is also asking for a price. The chances are that the estimates will be the same, although the following possibility enters: The sub-contractor may sense that he is not going to deal finally with a general contractor, but with an engineer purchasing agent, and in order to put himself in a better position, he will give a price closer to his final proposition than he gives to the general contractor; but this seldom happens.

With these separate estimates—which the engineer totals as against the general contractor's bid—the general contractor guarantees his estimate and the engineer does not. The engineer then calls in the plumber and the heating man and the others, whose estimates may have amounted to \$25 000, and says to them: "You can have this job for \$20 000." Perhaps they haggle awhile and it is finally closed for \$23 000. Then the purchasing engineer goes to the owner and says: "Here are the original bids that I received from the general contractor, and here is what I purchased it for; I have saved you 5 or 10%, and I have more than justified my fee." He has not done anything more than the general condition permitted both to the owner and the general contractor; but he has set up a false picture of conditions, and has created a myth that he can buy more cheaply.

There is no need to pursue the aftermath of this method of handling a building operation—its costly lack of co-ordination—because Mr. Christie has covered this phase fully. The speaker has no intention of suggesting that the engineer is not essential; he is very necessary. Nothing is more unpleasant for a general contractor than to be left to face the whims and misunderstandings of an owner without a competent engineer as an arbitrator; and the speaker always prefers to have a contract under the supervision of an engineer or an architect, provided he is competent and provided he has put his services on a professional basis and not on that of a purchasing agent.

<sup>11</sup> LAZARUS WHITE,\* M. A. M. Soc. C. E.—The speaker has had approximately thirty years' experience, about half of which has been as an engineer administering general contracts—mostly public works—and the remainder as a contractor—partly as a sub-contractor and partly as a general contractor; so perhaps his experience has been more rounded, or has covered a larger field than others.

As a sub-contractor, naturally the speaker might want to deal directly with the owner, so as to escape some of the hard general contractors; but in the interests of the owner himself and disregarding the special interests the speaker believes that the owner is better off with the general contractor. He certainly would be with the average class of general contractor.

The speaker's firm has often taken work directly with the owner, using the owner's architect (who is really his representative) or an engineer purchasing agent. They are very punctilious, and after making a plan, they are so proud of it that they will not depart from it. The general contractor has not prepared the engineer's or the architect's plans, and he is, therefore, much more free to depart from them. The result is that the owner does not get what he ought to get; he does not get the experience and advice of the different specialists that are on his building.

In one very glaring case, an architect prepared a plan for a contract which was taken directly from the owner. This plan passed the Building Department; it provided foundations for the larger columns, but not for the smaller ones loaded to 40 or 50 tons each. The owner would not put those in. He said the plan had passed the Building Department and must be all right, and this was an extra and he was not going to pay for any extras. What should be done in a case like that? A general contractor would have "ironed" this out very quickly. There would be a new foundation provided for the loads and an "extra" that would be in the interest of the owner.

Of course, this whole subject comes down to the beginning of the matter; that is, has the contractor an economic justification? If the contractor cannot justify himself economically, he deserves no special consideration; but after long experience the general contractor has survived. The reason is this, that by and large, the general contractor's profits, although in special cases they may be large, will average a rather low percentage.

The efficiency of the general contractor—a man of peculiar type, who has usually fought his way up and is one surviving of a great many—generally

\* Pres., Spencer, White & Prentiss, Inc., New York, N. Y.

is much higher than that of the owner, and is greater than the difference indicated by his fee. Suppose that he makes 5% on the general contract (3½% is more nearly correct). The owner, although he may be a very good clothing manufacturer, is not a very good builder. The fact that he is very good at something else probably means that he has not the ability of a general contractor, although he often thinks he has. He cannot make up that difference; he cannot make up the contractor's profit.

It is the same way with the engineer, who, of course, will naturally think that he can make up the difference of a contractor's profit because he designed the structure, and he has investigated conditions and thinks he knows all about it. Perhaps he does; but he lacks certain abilities. If the engineer designs the job himself, he may want to save the contractor's profits.

This also applies to public works, where the community, through the engineer, endeavors to do the work directly. If they can do it by that means more cheaply than through a general contractor, they ought to do it. The speaker will say that although it may destroy his business, but he does not believe they can do it more cheaply. He has seen too much of public work and the way the public business is conducted.

Necessarily, when he starts a job, the contractor has more freedom. He selects his men; he does whatever is necessary to get the particular men he wants. He builds up an organization, and that organization has to make good and knows it, and usually does. Public work is not managed on that basis. It has to be done with a public organization, plus a few additions, and the same efficiency cannot be obtained that is usually obtained by a general contractor.

In connection with public works the speaker would say that the general contractors on subway works are really general contractors. It would be difficult to segregate the different contracts. The excavation, steel work, etc., could not be segregated underground. The only alternative to a general contract would be for the public to do its own work, which has the objections that have been stated.

L. S. STILES,\* M. Am. Soc. C. E.—Some time ago, the Company with which the speaker is associated, was having a large structure erected under a general contract. The general contractor, naturally, brought in several miscellaneous trades. Had it not been for the experience of the men handling this contract, in co-ordinating the trades so that all lines worked together without overlapping or lagging behind, it is the speaker's opinion that progress with the structure would not have been as satisfactory as it was.

The speaker's work is not confined to building projects, but also includes equipping plants with all kinds of machinery and apparatus and other operations of a miscellaneous nature. Very often, under these conditions, it is found that the general contractor fits the situation. The work can be started later. The beginning can be postponed until such time as it is felt that the adequate facilities for proceeding with the work are there, and if it is then to be in the hands of a general contractor—a good co-ordinator—progress is made.

\* Constr. Engr., The Brooklyn Union Gas Co., Brooklyn, N. Y.

The speaker knows of many cases of owners of different kinds of business who have been very successful in their particular line. Some of them have attempted to do the requisite building themselves when expansion was necessary. They thought that the general contractor would be somewhat in their way and that he would be collecting money for work that they could do themselves.

However, he has never known an instance where the owner did not get into "hot water" before he was finished with the work. The owner has his sphere; the engineer has his sphere; and so has the general contractor; and they should not clash at all. It is true the owner should have a proper engineer, but what is really important is that none of the parties should overstep its own bounds. Companies that are enlarging their plants and facilities by extensions may engage, now and then, in the building business, but the general contractor is always in the business and, because of this, he has better relations with the trades. The average sub-contractor, in working on an extension or a new project, is apt to feel that, while he secured this order, he may not get another from the same owner. However, if he is working for a general contractor, he feels that he will have to make good, because when that particular work is finished, the contractor will have other projects on which he would like to be considered.

The speaker thinks that the attitude of the sub-contractor is different when he is doing business through the general contractor and when he is doing business through the owner, and that this is one of the great advantages of having a general contractor. He has never known a set of plans and specifications to agree, in every detail, with the finished job. The specifications never exactly include all the features that the owner hoped eventually to have built. Because of this, there is bound to be some over-reaching and some under-reaching, and the general contractor is far better fitted to "iron out" these difficulties than an owner himself would be.

The cost to install a certain item under a general contract is always more than the credit which would be allowed if it were eliminated. The speaker has had many particular instances of this. Not long ago, on a contract, it was decided not to buy a certain quantity of a certain item. The contractor was quite agreeable to the cancellation, but he still insisted that he should receive his profit on the cancelled item. This does not seem a reasonable demand.

The speaker has handled millions of dollars of contract work. It has been let out, sometimes by segregated contracts and sometimes through a general contractor, depending on the particular conditions, and both methods have proved satisfactory. The important thing is to be sure that both parties comprehend the project and that the work is organized in the proper manner. When, in the judgment of the owner's engineer, the scope of the proposed work warrants it, the speaker believes that a high-grade general contractor should be allowed to handle the job.

GUSTAVE R. TUSKA,\* M. A. M. Soc. C. E.—The question has been raised, as to whether the client is to rely on the general contractor or on the engineer

\* Cons. Engr., New York, N. Y.

for success in the work undertaken. The speaker has, at various times, acted as general contractor and, at other times, as engineer. The differences in the qualifications necessary for a successful engineer and a successful general contractor are fully appreciated. Nevertheless, it must be remembered that many successful contractors were previously successful engineers and received an important part of their training as such. There is considerable doubt as to whether they would have been equally successful contractors without such previous training.

In discussing this subject, it should be emphasized that all building construction does not belong to one class of work. The importance and magnitude of metropolitan building construction is fully appreciated, but there is a large amount of construction work concerned with special industries. This includes the various lines of factory construction where special machinery and special types of construction are required. In such cases the special experience needed to handle the work successfully is more likely to be found in the experienced engineer than in the general contractor.

From the discussion and from the cases cited by the author, one would be likely to reach the conclusion that most engineers handling construction work for their clients are exceptionally incompetent and that, on the other hand, most general contractors doing similar work are invariably absolutely reliable. Experience will show that there are efficient and inefficient engineers and capable and incapable general contractors and that, in the main, the success obtained will depend to a great extent on the kind of each class that has been employed on the work rather than on the class itself.

It may be of interest to contractors and engineers to know that both contractors and engineers have been described as experts using their best judgment, with the difference that the contractor backs his judgment with his own money, whereas the engineer backs his judgment with his client's money.

T. KENNARD THOMSON,\* M. AM. SOC. C. E.—This entire discussion reminds one of the discussions thirty-five to forty years ago when the statement was frequently heard that "engineers could not make good contractors". This was before so many engineers had become very successful contractors. At that time the speaker answered such a statement by saying that he could sit down and typewrite a letter, taking a long time to do it; but if he did so for months, he would be as quick as an ordinary stenographer; and, by the same principle, a good engineer was not a good contractor until he had learned contracting by hard practical experience. If he then found that he had good business as well as engineering ability there was no reason why he should not excel as a contractor.

This has been abundantly proved by the experience of many engineers. The main reason why general contractors are worth while is that they have learned their business, have their organization, and, in addition, are financially responsible for what they do.

On the other hand, if there is no general contractor, the person who does the work of a contractor is merely an agent of the owner, who could not be successfully sued by his client, and is often untrained for the job.

---

\* Cons. Engr., New York, N. Y.

H. M. DOUGHERTY,\* M. AM. SOC. C. E.—The author has covered part of a very large subject, but his paper seems to have been limited largely to the construction of buildings (which the speaker has always looked upon as the province and problem of architects), and to construction in the Metropolitan District. Possibly, this is only natural in New York; but it must be remembered that the broad field of engineering and the allied business of contracting extends throughout the United States and Canada; and that the American engineer, with New York as his base, does work in South America, Europe, Asia, and Africa. The speaker is possibly qualified to comment by twenty-five years' experience which, starting as a Constructing Quartermaster in the Army, leads successively through Engineer in Charge for the Contractor on Government contracts with the Bureau of Yards and Docks, and Engineer in Charge and Resident Engineer for the Contractor on public utility works, to Construction Engineer and Chief Engineer in charge of large construction works for operating corporations—this throughout the United States, in Hawaii, and in South America.

The speaker believes that the viewpoint of many contractors may be expressed as follows:

"We have grown into large contracting firms, and the Engineer, as an individual, is setting himself up as competent to do what we, as a corporation, advertise ourselves able to do; and what he, on account of professional ethics, may not advertise himself able to do. We feel that the Engineer as an individual must stay off the ground which we desire for ourselves. We as General Contractors will as, and if, necessary hire the Engineer; but we must be left alone in the field and the Engineer must be satisfied to be our employee; or the adviser and buffer between us and the owner."

In the case where the owner is not organized, or he cannot enlarge to take in construction; where he has not a purchasing department that he may bring to bear on the purchasing involved in construction; and where the life and size of the work are not such as to warrant him in purchasing or hiring the necessary equipment; the general contractor has not only a proper place, but a place which he fills with profit to himself and to the owner.

Where, however, the owner is an operating corporation which has a purchasing department capable of enlargement to take care of construction problems; where there is an organization which may be enlarged; and where there is work in hand which is either so continuous or of such size that there is warrant for investing in or renting proper equipment; a general contractor is out of place. For him to enter such situations complicates them and adds to the expense of the owner. The general contractor in these cases cannot use the knowledge of the operating force to the same full advantage as the individual engineer either in design or in construction; and the end is dissatisfaction both to the owner and to the contractor on account of the friction engendered.

That an engineer of wide experience may, with profit to these owners, be placed in charge of an engineering and construction department, taking the place of the general contractor, is to the speaker's mind not open to doubt or

\* New York, N. Y.

question. To lay down as a principle that the engineer of wide experience must move to the rear to make room for the general contractor, under any conditions, takes very debatable ground.

The experienced engineer of to-day is not simply a man of science, not a man skilled in one particular line. He is an organizer; a man competent to carry on the entire business of design and construction; to originate methods; to carry them out; and to protect his principal in the matter of contracts, purchases, and labor contacts.

In the field described as not suitable for the general contractor, the writer holds a distinct brief for the individual engineer; and that his ideas are not entirely wrong is attested by the fact that so many public utility corporations, mining corporations, motor corporations, steel corporations, etc., find it to their advantage to have a department in charge of a competent and experienced engineer, to carry on the work the general contractor carries on in the contractor's proper field, for the owner who requires and needs the contractor's facilities.

W. A. STARRETT,\* M. Am. Soc. C. E.—This paper addresses itself to the whole broad field of contracting, and comment, herewith given, refers only to that highly specialized branch generally known as large, metropolitan office buildings. Where such structures are under consideration, it has been the speaker's experience that the divided contract is most detrimental, and the unified, all-embracing contract is the only practical solution for the type of work in question.

It is true that certain architects, particularly those in the West, carry on, with considerable success, the function of the general contractor; but in doing so, they are, in effect, general contractors and are so organized. The risks to the owner may or may not be pointed out to him, but the responsibility must be obvious, and he evidently calculates accordingly.

Contrary to popular belief, contracting includes very little engineering work. If it were an engineering problem at all, it would be called business engineering, but the only point of contact between the two is that a knowledge of engineering is of value to a contractor but is in no wise essential, and it is likewise measurably true that wide experience in engineering in no way assists in considering the practical problems with which the contractor is confronted.

Successful contracting is based on wide experience and it is a most complex procedure in the field of tall, metropolitan buildings. As Mr. Christie has stated, the activity is almost wholly a managerial and co-ordinating function, but it also demands a going organization that is accustomed to "teaming" together, that understands the policies and precedents involved in the decisions and activities of the principals of the contracting company. The custom of the trade has a bearing. Contracting has grown up around sub-contracting, and it is beside the point to aver that it were better if this were not so. The whole trend of the industry is that the sub-contractor looks to the contractor for his contracts, his payment, his protection against injus-

\* Vice-Pres., Starrett Bros., Inc., New York, N. Y.

tice, and, most particularly, the skill of management which will enable him to get in, complete his work, and get out with a profit, not jeopardized by the risks of interference. From this situation has grown a relationship in which the best sub-contractors depend very measurably on the fair treatment and experience of the principal contractor. With one principal contractor a given sub-contract may be regarded as a hazard and risk, whereas exactly the same specified work may be considered without hazard if the general contract is handled by another and more favorably considered general contractor.

In spite of all the care that is given to predetermination and pre-planning, modern buildings are changeable and changing, even while under construction. The contracting system that gives this change the greatest elasticity without exposing the owner to disadvantageous claims is the best one. It is to be borne in mind that the desire for change almost universally arises out of the needs of the owner, seldom out of the needs of the sub-contractor. An owner represented by an architect on a highly subdivided contract is at a disadvantage when this situation arises. On the other hand, a sub-contractor depending on the general contractor with whom he may be doing business year in and year out, considers the question of changes and substitutions more equitably. Sub-contractors naturally look with suspicion on owners who have never built before and will possibly never build again. They fear that if they are thrown into direct contact with the owners, the latter may prove to be either capricious or arbitrary in their dealings. Generally, owners have no standing with the sub-contractors in their dealings and properly may be regarded with apprehension as an enterprise is undertaken.

Whatever is stated herein refers especially to private contracting. It is recognized that the Government civil agencies may not have the elasticity to deal with building problems that a private owner has. It may be expedient, apart from the mere practical question involved, for a Government to adopt any of a number of systems.

However, there seems no real justification for the separation of contracts where large, complicated structures are concerned and where the small fee paid to a capable general contractor for his services is so sure to be returned many-fold by the economies of service and administration that he contributes to the operation.

ROBERT RIDGWAY,\* PAST-PRESIDENT, AM. SOC. C. E.—The speaker is an engineer and not a general contractor. As Chief Engineer of the Board of Transportation of the City of New York, he has to do with the construction of rapid transit subways. The subway construction contracts may be regarded as examples of general contracts. The large construction contracts include all the items of work that make up the complete structure, such as excavation, concrete, water-proofing, and steel. They are let to the lowest bidder who can qualify, and he is made responsible for all the work to be done under the contract. He is the general contractor. The construction contracts do not

---

\* Chf. Engr., Board of Transportation, City of New York, New York, N. Y.

include track, station finish, or equipment, which call for work of special character, which work is done under separate contracts.

The subway work is generally divided into units of from  $\frac{1}{2}$  to  $\frac{3}{4}$  mile in length, and of a value of from \$4 000 000 to \$8 000 000. It is believed by the Board of Transportation that contracts of this size are the most advantageous because they are large enough to attract responsible concerns and not too large to restrict competition. There are exceptions to this rule where the conditions require it. For example, the under-river tunnels are let in units that sometimes cost from \$10 000 000 to \$15 000 000, or more. The largest single contract let to date is the tunnel under the East River at Fulton Street. Including its land connections, the bid price is approximately \$22 000 000.

It does not seem practicable to segregate these contracts; that is, to make separate contracts for the excavation, concrete, steel, and other items. If that were done the engineer would have to be the general superintendent in lieu of a general contractor, and there would be all sorts of interference between contractors, with resulting confusion, delay, and claims. Since they are public contracts, the Board of Transportation cannot follow the practice, common in private work, of choosing a number of qualified contractors and limiting the bidding to them. The work is open to general competition which means that the best qualified contractor is not always the low bidder, although the Board has been very fortunate in getting contractors of the character that it has. The Board has laid down the rule that the successful bidder must show liquid assets available for the job to the amount of 10% of his bid. This is to insure that the work will be carried on without the delay that always results from a lack of sufficient capital. The rule is a good one, and has the effect of eliminating those who are not financially able to carry the burden of the work. On only a few occasions, have contracts been awarded to other than the low bidder, and then only because the low bidder did not qualify.

A public contract is a rigid instrument and after it is entered into cannot be modified without an enormous amount of effort. Having this in mind the unit price form has been adopted for the subway contracts because that form provides flexibility and is believed to be fairer to both sides. A subway contract is a complicated one at the best. Not only must it take care of the building of the structure, but also of the underpinning of adjacent buildings and the restoration or reconstruction of all sub-surface utilities that exist under the busy streets of the city.

In other words, the street must be completely rebuilt, and provision must be made for paying the contractor for all this complicated work. Those who have had experience in this class of work know that it is almost impossible to predict what will be found under the surface of city streets. The ratio between quantities of earth and rock may be different from what is anticipated, and the quantities of the other items may be increased or diminished. This means that the contractor should balance his bid so as to provide for such contingencies. It is believed that the lump-sum form of contract would not be as fair because of the uncertainties.

Perhaps the speaker has strayed rather far away from the subject of this excellent paper, but he wants to point out that on the Board of Transportation

work the construction contracts are general contracts. If the segregated type of contract were used the engineer would have to act as the general superintendent or the general contractor, and, generally, he is not trained along those lines. It seems better to continue with the system now in use and have the trained contractor do the work instead of giving it to the engineers to do by day labor or by segregated contracts.

There are times, however, when one wonders whether a trial of another method would not be warranted as, for example, when a technical contractor goes to Court and wins a large sum of money, not on equity, but because a comma is misplaced in the contract. That money might have been saved if the work had been done by day's labor under the direction of the engineer. On the whole, however, the contract system is believed to be better.

R. E. BAKENHUS,\* M. Am. Soc. C. E.—The speaker's experience has been entirely in the State and Government service and, since 1901, with the Corps of Civil Engineers of the Navy, largely in connection with the construction work of the Bureau of Yards and Docks. It has covered all phases of contract work from the standpoint of the owner and the engineer; the owner in this case being the Federal Government. It has also been the speaker's good fortune to have had much experience in connection with the construction of public works by direct employment of labor and by the method of individual contract, thus placing the officer in charge in the position of the general contractor.

It has been, therefore, very interesting to note the author's views in regard to general contracts. There is no question that the building business in general could not get along without the general contractor; he is a very necessary part of it.

With any given project to be undertaken it seems necessary to make an individual analysis of the situation. There are a number of cases in which a general contract does not best meet the situation; perhaps they are only a few, a small minority of cases. One or two examples, of opposite extremes in regard to size, occur to the speaker. One, of course, is the Panama Canal, in which case the letting of the work by general contract was very thoroughly considered and finally rejected, and it was done entirely under the supervision of engineers, who originally had experience, of course, with day labor. The other example was the case of a small power plant which needed rehabilitation and enlargement. The appropriation was so small that the work could not have been accomplished had all the items been lumped under a general contract. It became necessary therefore to make a number of contracts which dovetailed into one another and included in individual contracts such items as the following: (1) Foundations for boilers; (2) erection of boilers; (3) boiler settings; (4) purchase of electric generators; (5) purchase and erection of engines as a separate contract, but including the forcing of the generators on to the engine shaft; (6) purchase of pumps in open market; (7) erection of certain piping and equipment; and, (8) construction of new wing to boiler-house.

\* Capt., C. E. C., U. S. N.; Public Works Officer, Navy Yard, Brooklyn, N. Y.

It meant much work and anxiety on the part of the engineer to handle the work in this way, but it was done successfully in this instance at a large saving in cost and without so much as a question about a single item throughout the progress of the combined work. The total cost of the Panama Canal was about \$400 000 000, and that of the power plant just mentioned about \$40 000.

Another instance in which the general contract did not seem to be advisable was the construction of the U. S. Naval Armor Plant at Charleston, W. Va. The decision to proceed with the construction of the plant was reached by the Secretary of the Navy in August, 1918, during the latter part of the World War and at a time when the naval building program was in progress. Orders were issued to prepare the designs which were completed during the next few months, and then further orders were given to go ahead with the construction work. In the meantime the Armistice had been declared. At that time the markets for labor and material were in such an uncertain state that the Department did not feel that the general contractor would be able to give a fair lump-sum bid. He might either over-estimate or under-estimate the conditions as to labor or material or both. A "cost plus" contract did not seem wise because it was a rather unpopular form in the Government service at the time. Therefore, the only decision left, as recommended by the speaker, was for the Bureau of Yards and Docks itself to become the general contractor.

Such factors as the steel frame work, steel sash, roofing, and a few minor items were made the subject of individual contracts. All the other parts of the work, including excavation, concrete foundations for buildings, furnaces and machinery, brick work, railways, roads, sewers, water piping, and electric installations were undertaken by the direct employment of labor. As the Navy Department had no organization at Charleston for such work, it became necessary to purchase equipment, establish a labor office, and purchase material as well as secure transfer of materials from other points where it was no longer needed by the Government service.

The work undertaken cost more than \$10 000 000 and was completed successfully, on time, within the limits of funds available. It is hardly likely that such a result could have been accomplished at that time by any other method of construction. So far as known, it is the largest single enterprise in the line of public works construction, which the Navy Department has ever carried through as one operation.

It is very necessary to emphasize that for any project it is desirable to make a thorough study of the situation as to how it shall be carried through and then decide what is the best means to accomplish it. In such a situation there must be taken into account not only the project itself, but also the personnel that would be available to handle it; the market condition as to labor and material; and what general contractors are available and able to handle the project under consideration. Above all, it is necessary to take into account the experience of the engineers or other personnel who would be placed in charge of the work, either under the contractor or under direct execution by the owner. In the three cases which have been mentioned by the speaker, it

has been shown that there were particular reasons why the general contract was not the method adopted.

There is no question that in the majority of cases the general contractor has the experience and ability to carry through complicated or simple construction work better than it can be done by the owner or engineer. The various reasons for this have been so clearly brought out in the paper that it is not believed necessary to repeat them.

Some of the larger corporations, as well as the Government service, have construction problems which are of a continuous character, such as railway maintenance, railway sidings, roads, and telephone and telegraph communication systems, and it has been found advisable in some of these cases to organize a permanent construction force under the control of a trained official of the organization.

The usual owner or engineer of to-day, aside from the great corporations or Governmental organizations, has a great many other things to do than to take the part of a general contractor, and usually he has not the organization or the personnel that the general contractor develops and maintains, with the special knowledge and experience that must be a basis of any attempt to do general contract work. Any owner or engineer who undertakes, seriously, a project in this way without previous experience, and qualified personnel, will have many snares and pitfalls to avoid, and his experience may cost him much from the most unexpected causes. However, the Engineering Profession has given many examples of successful transition into the general contracting business.

It seems well to remember that the engineer is usually charged with more than the design of structures and projects, and the preparation of drawings and specifications. Generally, he is the one who should make the analysis of the situation on which a decision may be based as to the best method of carrying the project from a status of drawings and specifications into a completed plant or structure.

WILSON T. BALLARD,\* M. Am. Soc. C. E. (by letter).—The author has discussed a subject of great interest and importance in these days of large construction projects. He announces an effort to throw some light on the subject of the general contract and the segregated contract. He then dismisses the subject of the segregated contract in a few words, by defining it and stating that certain engineering projects, by their nature, are satisfactorily handled by segregated contracts, and proceeds with a detailed discussion of the advantages of the general contract with especial emphasis on its value in building operation. Therefore it seems worth while to bring out in discussion more concerning the segregated contract and, further, to consider certain modifications of the general contract that may broaden its scope of usefulness.

Little, if any, criticism can be offered of the statement that the general contract, in practically every instance, is the better of the two forms for building construction. In the construction of most large buildings a great

\* Vice-Pres., The J. E. Greiner Co., Baltimore, Md.

number of small sub-contractors are employed, many of whom are hardly more than groups of highly specialized laborers whose efforts must be properly timed and co-ordinated.

There are many kinds of projects, however, outside the field of building construction. One group of great importance includes the building of large bridges. Each big bridge project divides itself naturally into the construction of substructure and superstructure which, except in the case of arch bridges, are totally different operations and are performed by different kinds of organizations. Frequently on a bridge of any size, the contractors on the substructure and superstructure are each competent and financially responsible. If, in such a case, one or the other occupies the position of general contractor, he does not perform a service of appreciable value in supervising the work of the other. Therefore, the owner is best served by carefully drawn separate contracts awarded to contractors of proven capacity and ability, thus avoiding the payment of double profit.

There is one qualification of the foregoing that, when made, brings work such as described back into the hands of a general contractor without calling on the owner to pay a commission or fee and receiving no commensurate value therefor. This qualification requires that the contractor who assumes the work under a general contract modify his commission in such a way that it is not made to apply to the value of work done by a large sub-contractor whose ability and financial responsibility are equal to or greater than his own. For instance, assume that A, a competent company on foundations, takes the general contract and sublets the steel superstructure to B, one of the large steel companies. A's contract provides that he must deliver the piers at a certain time, after which the company furnishing and erecting the steel must do its work. During this period of steel erection, A has little if anything to do and maintains practically no organization on the job. It would be unfair to the owner therefore for him to include in his fee paid him by the owner an appreciable, if any, percentage of the value of the work done by the steel company since such a charge on his part would constitute a duplication of profit paid by the owner. This applies to other than bridge construction where the work, by its nature, divides itself into two or three large and distinctly different operations.

A further point discussed by Mr. Christie with reference to the 3 or 4% charged by the engineer or architect for supervision during construction, might well be considered. Ordinarily, supervision during construction does not contemplate co-ordination of contractors' functions, but rather is furnished in order that the owner through his agent, the engineer, is assured that all work done is according to plans and specifications. This charge, therefore, does not represent a duplication of profit or fee for general supervision, but rather is compensation to the engineer for a distinct and separate service and one that is indispensable, especially where part or all of the money being spent comes from the investing public through the medium of bankers.

WARD P. CHRISTIE,\* ASSOC. M. AM. SOC. C. E. (by letter).—This paper, which set forth the advantages of the general contract to owners, has developed many interesting and valuable observations. The writer feels indebted to all those who took part in the discussion for having contributed their time and constructive thought to this rather spiceless subject. He would like to respond to the courtesy of discussion by acknowledging each individual observation, but that is not feasible.

Some of the discussion indicates that the paper was interpreted to raise an issue between contractors and professional engineers with respect to the two systems of contracting, but this was not its intent. Such issues as do exist were not assumed to involve the professional man as one party, but to rest principally between two groups of commercial organizations. It is not clear to the writer how a professional engineer can be a fixed proponent of one contracting system on all occasions, unless he ceases to remain professional, or begins to commercialize his profession.

In several parts of the discussion resentment cropped out against any thought that engineering ability, *per se*, does not qualify one to manage construction; and this thought might profitably be developed, but there are so many current conceptions of engineering, that the subject becomes hopelessly confused. It appears advisable, therefore, to eliminate this point as far as possible in comparing the two contract systems. This may be done by assuming that any competent engineer is capable of performing the services of a responsible general contractor.

Since it is not practicable to deal with all the views expressed, the writer's closing discussion is confined to five points which appear to be in need of emphasis or further clarification. They are as follows: (1) Judicious Selection of a System; (2) Engineering Service; (3) Construction Service; (4) Liability of Owners; and (5) Ethical Considerations.

*Judicious Selection of a System.*—In view of the conflict of thought which usually attends a discussion of contracting methods, the clear observations of Professor Lyle are pleasing. He makes the point that construction projects vary in character from those that are obviously suitable for one system to those that are obviously suitable for the other, and that between these extremes are projects which necessitate, in the selection, an individual exercise of judgment.

An example of a project clearly requiring the general contract is the subway job mentioned by Mr. Ridgway. Its many different parts are so closely interlocked and its management so specialized that segregation into separate contracts would place an enormous risk upon the public body. Probably each contractor would be obliged to include a heavy contingent allowance in his bid to cover the hazard of poor co-ordination.

An example of the other extreme involving little hazard to an owner, is a steel bridge, such as that mentioned by Mr. Ballard, for which the work is physically separated into various parts, which are not built simultaneously. On a project such as this no great degree of co-ordinating management is necessary. Each contractor could work without interference from others, and

\* Engr., The Associated General Contractors of America, Washington, D. C.

such interlocking as occurred between abutments, superstructure, and roadway surfacing, could be handled without placing material risk upon an owner.

It should not be inferred from these examples which illustrate only the feature of risk to an owner, that a general contract is unsuitable to projects that lack the characteristic of interlocking. Numerous other factors are involved in a judicious selection, and they can only be judged by considering the circumstances which attend the specific project. Some of these factors are as follows:

- (a) Magnitude of the entire project and its component parts.
- (b) Availability of equipment and duplication of contractor's outfits.
- (c) Competitive conditions in the general and specialized contracting fields.
- (d) Sources of labor and duplication of labor camps.
- (e) Necessity for speed.
- (f) Relative prices as shown by actual bids.

If a contract system were selected according to a judicious weighing of these factors, probably the issue between general and separate contracts would disappear. The issue does not usually arise from disagreement as to the need for co-ordinating management, but from disagreement as to who should perform that service.

Some engineers desire to perform it because they believe they can manage the job and save money for client or employer; some have had unsatisfactory service from general contractors; others are disgusted with the way that some contractors treat their sub-contractors; but in a great many cases separate contracts are used because of self-interest of the agency that has the decision. Some one is interested in expanding or solidifying his job, gaining experience to enter business, or performing the general management for a commission.

If the paper did reflect the categorical "no" for separate contracts, to which Professor Lyle objected, it was an unconscious reaction to the categorical "yes" of many who sell their services or hold their positions through that system. His advice against becoming proponents of either system, sound as it is, will conflict with the self-interest of this class. They are undergoing or have completed the transition from profession to business.

Individuals or firms that desire to engage in the business of construction management, without entering the field as contractors, must become proponents of the separate contract system. Their services are as inherently linked with that system, as a general contractor's are linked with the other. Therefore, except in those cases where decision is in the hands of a professional engineer, who is not desirous of managing construction for financial gain or experience, judicious selection of a system with respect to the clients' or employers' interest is not likely to be the rule. It is too closely linked with the question of profit, commission, or salary.

*Engineering Service.*—A number of observations made in the paper were based on the assumption that those who call themselves engineers are engaged in the practice of a profession. Otherwise, the discussion becomes irrational. If it is actually desired to clarify the separate-contracts issue, rather than confuse it, a distinction must be made between professional engineering and the many business activities that have borrowed its name.

According to Webster a profession is "a calling in which one professes to have acquired some special knowledge used by way either of instructing, guiding, or advising others, or of serving them in some art". This is a definition that seems to fit the men who, in former years, were called engineers. Those who design construction projects and who supervise their building are undoubtedly doing professional work, if the purpose of supervision is to see that a client obtains what he bought. They have no personal interest in recommending a specific material or system of contracts and are not in such a position that their advice to a client or employer could be influenced by any possibility of their financial gain or loss. These appear to be the basic characteristics of a profession.

When this conception of professional engineering is compared with Mr. Dougherty's definition of an engineer, it would seem that the two bear very little relation to each other. The latter does not appear to describe those men who are the backbone of the Engineering Profession. It fits more closely those who have left the practice and have entered into business.

During the last decade many men who were engaged in the profession of engineering have developed themselves along the line of construction management. They are operating either as contractors, in the generally accepted sense, or as construction managers, under the appellation of engineers. Some who are strictly business executives and completely out of touch with matters of the profession, still cling to their earlier title and inflate the definition of an engineer to fit their later accomplishments. Apparently, the title of engineer is a garment of respectability which one is reluctant to lay aside when he emerges from the profession into the supposedly less respectable field of business.

Such juggling of terms, however, should not obscure the fact that engineering as understood by most of the world is a profession which requires its particular type of mind and ability. It is a most honorable and useful vocation, but proficiency in engineering does not of itself equip one for construction management.

The fact that some individuals pass from engineering into business and succeed, should not delude engineers as a class into thinking that every competent member of the profession can do likewise. The field of construction management and that of engineering are vastly far apart, and few individuals are able to master both. The professional engineer, therefore, should move cautiously when he decides to experiment with separate contracts. He may well pause and consider whether it is ethical for him to acquire his business experience at the risk of some one else, for he is risking his client's or employer's money and not his own.

*Construction Service.*—Two principal types of construction service are furnished by firms calling themselves either engineers or contractors. One is based on the separate contract system and the other on the general contract. Either may include both design and construction, but this has no particular bearing on the nature of the construction function itself. The one based on separate contracts does not include collectible guaranties, but it protects an

owner's interests to the extent of the skill and integrity of the constructing firm. The one based on a general contract gives not only the protection of skill and integrity, but also that of financial responsibility. It includes guarantees covering time of completion, claims, and cost of the project as a completed whole.

Performance of either of these services in a proper manner is an honorable vocation, but one should not be recommended to a client or employer when the other will serve his interests better. If an owner has a definite limit to the amount he may invest in construction, and cannot afford to take a chance on an over-run of cost or damages, he should obviously have a service that will absorb the risk of such occurrences. This can be practically provided only by the use of a general contract. On the other hand, if the owner is not limited to a definite expenditure, and is willing to assume the risk of management, then the separate system fits his needs.

At present, separate contract service is extensively identified with firms called engineers and the general contract with firms called contractors, although on occasion either one or both services may be supplied by the same company. The firms themselves are practically alike, except that some of the directing heads were once engineers, while others grew up in the ranks of business. Irrespective of what they call themselves, the successful ones are headed by competent business executives, and not by professional engineers.

Some of these firms offer various types of super-construction service, dressing them up as professional services; but one is only fooling himself if he thinks that construction management is not a business; and he is certainly fooling his client if he represents it as a profession.

The unvarnished fact is that these super-services are composed of two elements: One is design, furnished by professional men; and the other is construction management, performed by business executives. The fact that designers and managers are associated in one firm does not alter the kind or amount of service necessary for a construction project. It does not eliminate either the fee for design or the fee for management. These fees are merely combined as one and paid to a single concern.

The really significant feature of the super-service is that both the mistakes of engineering, and the shortcomings of management "come home to roost on the same perch". When the job does not progress properly, the firm that combines both design and construction has no one to whom it can "pass the buck". This may be a great advantage to an owner, if he is using a general contract, as any loss from mismanagement will then fall on the constructor; but if he is using separate contracts, the super-service avails him nothing. The managing agency does not assume any over-run of expense, and the loss will fall on the owner.

The significance of these circumstances is readily perceived when one learns what has been decided about the owners' responsibility by the Courts.

*Liability of Owners.*—Legal aspects of the two contracting systems were treated briefly in the paper; but there was practically no discussion of this subject, and it is of most vital concern to owners. The fact does not seem to

be generally known that various warranties, which do not concern public or private owners under a general contract, are placed upon them when the work is divided among independent contractors.

On certain types of projects, on which one contractor is sure to complete his work and be out of the way before another is due to begin, this responsibility may be of little consequence, but on other types it becomes a serious matter. If the work of the various contractors must proceed simultaneously, or if the progress of one depends upon the performance of another, the owner has a legal responsibility for synchronizing and co-ordinating their operations. It is his duty, exercised of course through an agent, to see that no one of the independent contractors injures the work or impedes the progress of another. These conditions are implied toward all, and the Courts have held him accountable.

Naturally, if the managing agency is capable and experienced, it can greatly minimize the risk, but no amount of skill or experience can insure that valid damage claims will not arise. Such insurance can be given only by some agency that is financially able and willing to absorb the loss.

A very clear example of how claims originate merely through interference of one contractor with another is found in the case of the Edge Moor Iron Company *vs.* United States.\* The Iron Company had a contract for furnishing and installing certain boilers upon foundations which were being built for the Navy Department by another contractor. Each had a separate contract with the Government. The work was not complicated, and there was not much interlocking with respect to time or position; in fact, the project was one requiring a minimum of co-ordination.

The foundations were not completed according to a schedule such that the Iron Company could carry out its work in a manner inferable from its contract, and it was subjected to considerable delay. This delay, which increased the contractor's expense, constituted a breach of contract on the part of the Government, thereby establishing valid grounds for claim. Mere extension of contract time did not compensate for the delay.

In rendering a decision, the Court of Claims pointed out that, although the foundations were not built by Government forces, the Government could not escape liability. It had breached a condition necessarily implied by the separate contracts, that it would co-ordinate the work of all contractors so that each might perform his part as indicated by his contract.

The Edge Moor decision and other similar ones rendered by the U. S. Supreme Court and the Court of Claims demonstrate that separate contracts contain a serious loophole for claims. If any one of the contractors is of the kind that makes his profit out of suing on technicalities, he can cause trouble on almost any job of interlocking parts. When a suit does occur, the owner's only hope of avoiding loss is that of suing his own agent or a delinquent contractor. Possibly the delinquent contractor may have been unavoidably delayed.

In such cases the contractor's defense is very often made secure by some complication of circumstances or by technicalities which involve the engineer.

\* 61 Ct. Cls. 392.

It is not unprecedented for a number of suits to grow out of a single job. Such occurrences would probably be more frequent were it not for the fact that a responsible contractor ordinarily would rather take a loss than go to Court.

There is no practical way to eliminate the hazards of these circumstances through the wording of contracts. It has been tried repeatedly without success. If the provisions are made "tight" enough to block claims that might arise from separation of the work, they are so "tight" that responsible contractors often decline to bid. If they do bid, they must include in their prices an extra allowance for contingencies.

This situation is partly responsible for the development of the general contract. It serves as a sort of contingency trap to catch all the overcharge, short, and damage claims arising from the complexity of the work. Under this contract any judgments obtained by the specialized contractors or others must be satisfied by the general contractor or his surety. They are hazards under the system.

*Ethical Considerations.*—The paper was characterized by Mr. Muhs as a complaint that "engineers, by a system of segregating contracts, are usurping the functions and encroaching upon the field of the general contractor". This is a surprising reaction, because such complaint as may have been readable between the lines was not for general contractors. It was for those many men who respect and practice the profession of engineering.

General contractors are not fearful that the need for their services will be eliminated by separate contracts. A few more outstanding failures on public buildings, on which inexperienced men are experimenting with this system, will kill it in the public field. If it should become predominant in private work, contractors will merely adopt the system. If necessary they will associate professional engineers with their organizations, and render both design and construction service. There is nothing mysterious about it that gives a monopoly to management agencies called engineers.

What causes contractors to condemn separate contracts is not a loss of business, or even the nature of the system itself; but the misstatements or ignorance by which owners or employers are frequently induced to use the system. Owners are commonly told that separate contracts provide them with a service as complete and as fully protective as that of the general contract; and that they can eliminate the services of a general contractor and save the expense of his service. Such statements are subtle and dangerous misrepresentations, which many owners are unable to detect.

When an owner is willing to assume the risk entailed by separate contracts and accepts the proposition with full knowledge of their character, no one can have any just complaint about their use. It is a matter of importance only to those directly concerned in the transaction. However, if the owner is induced to use the separate system through statements that it places no more risk and responsibility upon him than does the general contract; or, if an engineer, with no experience in construction management, represents himself as competent to replace an experienced contractor, then a question of ethics is clearly involved.

Such practices are misrepresentations of kind and quality that fall into the same category as the misbranding of commercial products. They are no more related to honorable business than are the actions of some contractors who skimp their work or undertake projects which they know they cannot perform.

For a number of years complaint against the methods used in promoting separate contracts has been growing, but, since the profession has taken no great interest in the matter, and since many contractors had hands that were anything but clean, the subject has had very little frank discussion. It is no longer a matter of concern only to the owner and his engineer. It concerns both the business of contracting and the profession of engineering. From the discussion, it is evident that the basic need for analysis is not on the theory of the systems, but on ethical practice for their use. It is not beyond the possibility that the profession is losing its prestige through the aspirations of members toward business, and through the practices of some who have already made the transition.

To any one who may imagine that the paper was merely a plaint of contractors, or that there is no real question of ethics involved in the use of separate contracts, the writer commends a reading of Section 2, Part III, of the Society's Code of Practice.\* It is as follows:

"The Engineer shall call the owner's attention to the fact that under a general contract for a project the Contractor assumes large responsibilities for organization, co-ordination, and management which, under segregated contracts, must be borne by the Owner or Engineer. Further, that in many cases a general contractor, with control of and responsibility for these phases of organization, co-ordination, and management, may secure economies of costs and time in the benefits of which the Owner will share."

### Paper No. 1725

#### CROWN STRESSES IN A SKEW ARCH\*

By J. CHARLES RATHBUN,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. B. F. JAKOBSEN, EDWARD GODFREY, AND  
J. CHARLES RATHBUN

#### SYNOPSIS

The purpose of this investigation was to devise a method of finding the stresses at the crown of the ring of a cast skew arch model and to check the results obtained by laboratory experiments with those obtained by theoretical calculations. Unfortunately, the opportunity did not present itself to rebuild the apparatus in order to produce better results and as such an opportunity does not appear imminent, the data thus far obtained are presented for consideration. This investigation has grown out of a study made by the writer in 1923-24.‡

The analysis presented at that time was of a purely theoretical nature. The writer was unable to find experiments either refuting or corroborating the work; nor did the discussions of the paper cite any experiments or theory that could be used as a check. The writer hoped to check the various deductions by a continuation of these experiments, but this has not been practicable. A study of the effect of horizontal loads§ is of especial interest as brought out by A. H. Beyer, M. Am. Soc. C. E.

#### GENERAL

In order that the notation used herein and in the Appendix may be more easily understood, Fig. 1 from the 1924 paper is reproduced as the writer's Fig. 1.

\* Published in February, 1928, *Proceedings*.

† Prof., Civ. Eng., Antioch Coll., Yellow Springs, Ohio.

‡ "Analysis of the Stresses in the Ring of a Concrete Skew Arch," *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p. 611.

§ *Loc. cit.*, p. 657, Conclusion (e).

In the present experiments, arches cast from plaster of Paris were secured in a framework made for the purpose (see Figs. 2 and 3). One abutment was held as rigid as possible while the other was secured to a steel frame. To this frame were attached six dynamometers or spring balances by means of which the reactions of the free abutment could be obtained. At two positions on the arch ring steel collars were clamped. These positions were considered as the abutments of the arch ring for the purpose of computation. The dynamometers were adjusted as the load was applied, so that the two collars remained in the same position relative to each other throughout the test.

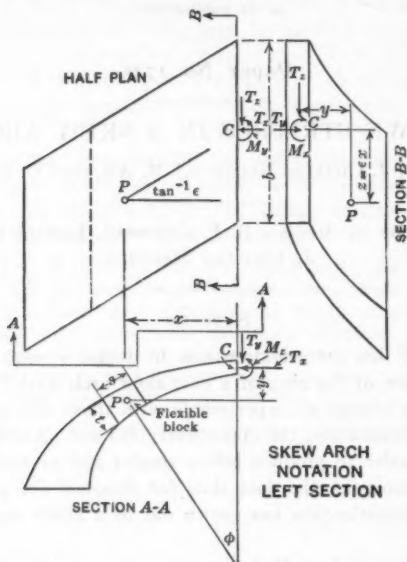

FIG. 1.

Of necessity, in considering the stresses in the ring of a skew arch the magnitude, direction, and location of forces in space must be considered, in contradistinction to forces in a definite plane, as in the right arch theory.

To define the resultant of a system of forces completely requires only six quantities. These may be taken as the components parallel to any three assumed rectangular axes and the moments about these axes. As all these quantities are mutually independent, the six are necessary as well as sufficient, and it is, therefore, important to have six and only six independent dynamometers to determine the location of the force produced by the thrust of the arch ring.

Again, to determine the position of a body in space requires six independent quantities, three to locate the position of a point in it, and three to determine the amount it is rotated about each of three perpendicular axes. These quantities are also independent.

Therefore, in an experiment of this character, all six components of the abutment reaction must be observed and all six possible movements of the abutment guarded against.

#### MODELS

The models used were made of plaster of Paris mixed with 60% (by weight) of water. This mix was decided upon after a number of experiments with varying water contents. The value of  $E$  was found to vary greatly with the proportion of water used, being about 400 000 lb. per sq. in. when equal parts by weight of water and plaster (100%) were used and 1 100 000 lb. per sq. in. when one-half this quantity of water was taken. Thus, it is quite obvious that great care must be used to secure a uniform mixture. If the mix was too rich the rate of set was rapid and the tendency to lump was considerable. The result, however, was a much stronger material. It was finally decided that the least quantity of water that could safely be used, was 60%, by weight, of the plaster. For the sample of plaster of Paris used in this work this percentage gave ample time to mix the batch, work out all lumps, pour it into the mould, and remove the entrained air before the initial set. At the same time the resulting model was strong enough to withstand rough handling.

A mixture of plaster of Paris and water proved to be a very satisfactory material for the purpose of studying stresses in a model with the view of applying the information thus obtained to a study of stresses in a larger concrete structure. Being a cast material it has somewhat the same characteristics as concrete and when mixed with care is very uniform in quality. After being cast, a model can be sawed or cut with a chisel or plane. This property was very valuable in shaping the skew arch rings.

The ring was cast as the segment of a cylinder with an inside radius of 12 in. and an outside radius of 12½ in. The form for the intrados consisted of a sheet of galvanized iron held in a semi-circular shape by a wooden frame. Two pieces of ¾ by ¾-in. rubber packing were laid on this form a distance apart that would insure sufficient material for trimming the completed model. Over these was placed a piece of galvanized sheet iron as a form for the extrados. This was fastened by bolts attached to the edges and screwed to braces over the wooden frames. Thus, the two pieces of sheet iron were held securely ¾ in. apart. The form was then turned completely over, and the arch was cast by pouring the soupy mixture in one side and letting it rise to the other side. A wire was threaded through the forms and worked back and forth to remove any air pockets that might be present. The sheet iron was greased to prevent the plaster from sticking to the forms. The arch was allowed to set 24 hours before the forms were removed.

Lines were drawn on the outer sheet of iron with a soft lead pencil. These lines were laid out as a rectangular grid before the sheet was bent over the forms, and the sheet was placed so that one set of these lines was parallel to the axis of the barrel of the arch. The crown and lines parallel to and 60° from it were particularly noted. When the forms were removed the lines were found plainly marked on the model and aided greatly in truing up and setting it.

The rubber packing when laid on the circular form did not lie in a plane, of course, so the model had to be trimmed. This was done by clamping a thin board to the arch so that it was tangent at the crown line and skewed to the axis of the barrel. The model was then laid on a table with the plane of the board perpendicular to the table. Two lines were scribed on the plaster parallel to the table surface. These lines marked the two sides of the completed arch ring. By using an ordinary hand-saw with coarse teeth, the ring was sawed close to these lines and then trimmed down with a carpenter's jack-plane.

Thus, the completed model consisted of an arch ring of a cast material with a low modulus of elasticity and considerable strength. It was formed by the segment of a cylinder subtending an arc of  $120^\circ$  and was limited by two parallel planes, which make an angle of  $(90 - \epsilon)$  with the axis of the barrel of the arch,  $\epsilon$  being the angle of skew.

The lines  $60^\circ$  from the crown were used to set the collars for recording abutment deflections.

#### APPARATUS

One of the fundamental assumptions in the arch theory is that the relative position of the abutments does not vary. In designing the testing apparatus it was necessary, therefore, to be assured of this condition and, at the same time, to be able to record the six components of the abutment reaction.

The arch ring proper was considered to lie between the two collars that were clamped to the arch ring. (See Figs. 2, 3, and 4.) Each of these collars had contact with the ring at four points by means of sharp screws resting against fiber washers. The washers rested on the arch ring at the centers of the four sides of a section of the ring. In order to be sure that the collars maintained the same position relative to each other, six independent points of contact had to be maintained. This was done by means of a system of levers. The left collar had attached thereto an arm that reached to within  $\frac{1}{8}$  in. of another arm attached to the right collar. In this space was inserted a steel phonograph needle sharpened at both ends. To the needle was attached a stiff wire pointer, properly counterweighted so that the center of gravity lay at the center of the needle. The end of the pointer was in line with the axis of the needle. A short wire was attached to the nearest collar and the free end was adjusted so as to mark the initial position of the end of the pointer. By this device a movement, either vertical or horizontal, of one end of the needle relative to the other, was multiplied  $\frac{17 \times 8}{5}$ , or 27.2 times. To the right collar

were attached two arms which also engaged phonograph needles in a similar manner. These two needles were placed so that their axes were in line. Thus, there were three needles, each recording two motions, making a total of six independent points of contact between the two collars. To show that they were independent it is only necessary to demonstrate that each needle could be moved either vertically or horizontally without affecting any of the other five settings.

A rotation of the right abutment relative to the left about a line joining the points, farthest from their respective pointers, of Needles Nos. 2 and 3 would give a vertical movement only to the pointer of Needle No. 1 without affecting the setting of the other two pointers. A result similar to that obtained for Needle No. 1 could be obtained for Needles Nos. 2 and 3. A horizontal rotation of the right abutment relative to the left about the vertical

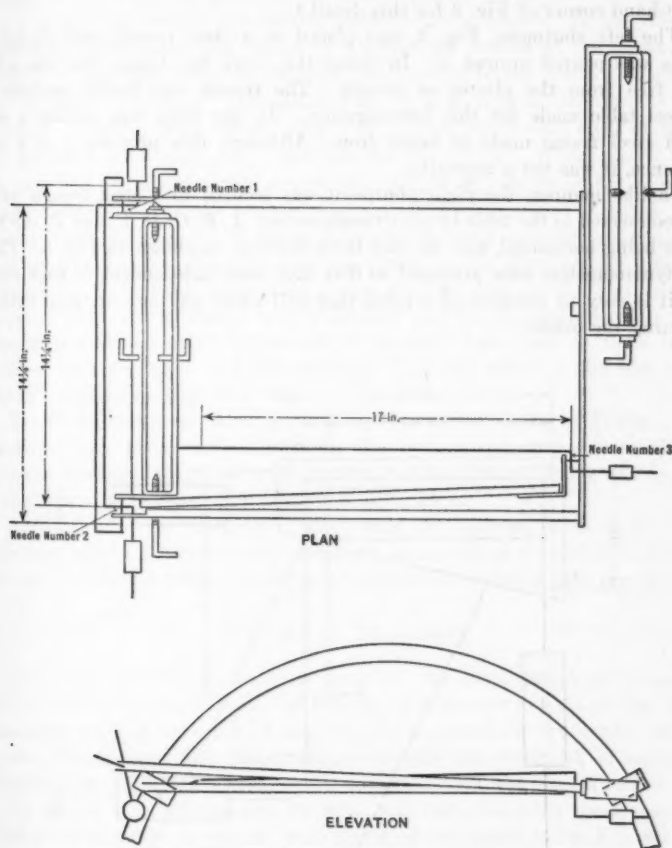

FIG. 4.—DEVICE FOR RECORDING MOVEMENTS OF ABUTMENT.

line formed by the intersection of the planes perpendicular to Needles Nos. 2 and 3 and passing through the one of their points in contact with the right abutment, would give a horizontal movement to the pointer of Needle No. 1. Similarly, for Needles Nos. 2 and 3. For Needle No. 3, it is to be noted that the axis of rotation is at infinity. This does not affect the result.

The load used was a concentrated load placed at the center of the crown. The method of loading is shown in Figs. 2 and 3. A  $\frac{1}{2}$ -in. cut washer was placed on the arch ring, and on this was placed a  $\frac{1}{2}$ -in. nut, in which was a stud with the end rounded off. The pipe that was used as a beam to apply the load was flattened by filing slightly where it rested on the stud. The ends of the pipe carried milk scales for dynamometers. The load was applied by inducing a force on the scales with a hook-bolt and butterfly nut. (See lower right-hand corner of Fig. 3 for this detail.)

The left abutment, Fig. 3, was placed in a steel trough and plaster of Paris was poured around it. In doing this, care was taken that the collar was free from the plaster or trough. The trough was bolted securely to a steel table made for this investigation. To the table was welded a very rigid steel frame made of angle iron. Although this property was a convenience, it was not a necessity.

In like manner, the right abutment was secured to a steel trough which was connected to the table by six dynamometers, *A*, *B*, *C*, *D*, *E*, and *F*, the first three being horizontal, and the last three vertical, as shown in Fig. 5. These six dynamometers were arranged so that they were independent of each other, for it is easy to conceive of a force that will affect any one of them without affecting the others.

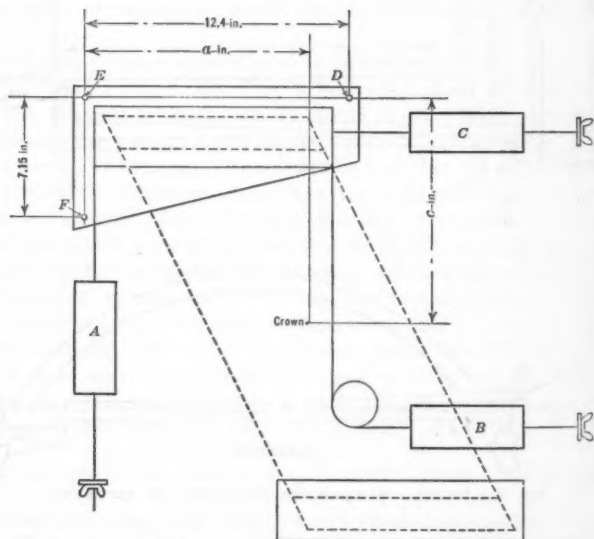

FIG. 5.—LOCATION OF DYNAMOMETERS WITH RESPECT TO CROWN OF ARCH.

The scales were adjusted after each increment of load was added until each of the three pointers was at its initial position; therefore, the collars remained in the same relative position to each other throughout the experiment and any

deflection due to lack of rigidity of the table, frame, troughs, or arch ring from trough to collar, was taken up while adjusting the scales.

#### METHOD OF PERFORMING EXPERIMENT

After the model was trued up, as previously described, the collars were placed in position on the marks drawn for them. The free trough was then blocked in place on the table, at the same elevation as the fixed trough and in a position that allowed the vertical scales to hang plumb. It was clamped securely and the model was placed in the troughs, leveled at the crown, and oriented so that the barrel of the arch was parallel to the plane through the axes of Scales *D* and *E*. The portions of the arch ring in the troughs were thoroughly wetted, after which plaster of Paris, mixed with 60% of water, was poured around them until the troughs were filled. When placed thus, the arch had no initial stress, except that due to its own weight. After the plaster had set 24 hours the needles were placed in position and adjusted. The loading beam was then placed across the top of the arch and the dynamometers were hung therefrom. Enough load was placed on the dynamometers to hold them steady. The load then on the crown was less than 10 lb. The dynamometers at the right abutment were tightened and the clamps removed. They were then adjusted until all the needle pointers were back to their initial position, both vertically and horizontally. This was taken as the zero crown load in constructing Figs. 8 to 12.

The crown load was added by small increments as shown in Tables 1 to 6, inclusive, and, after each increment, the dynamometers were re-adjusted. This was continued until the capacity of one of the dynamometers was reached, or the crown load exceeded its initial value by 50 lb.

Although the re-adjustment of the needles by applying loads to the dynamometers was in the nature of solving six equations in six unknowns by the cut and try method, after a little practice it could be done in a few minutes.

#### PRELIMINARY EXPERIMENT

After the preliminary work to ascertain the most satisfactory mix for plaster of Paris, an experiment was considered necessary to gain an idea of the maximum vertical crown load that could be placed on the model without injury. From these data the testing apparatus was designed, or more particularly, the capacity required for the dynamometers was ascertained.

To obtain this information an arch was cast, the ends were placed in notches cut in a 2-in. board and were plastered into place. (See Fig. 6.) The board and arch were put on a platform scale and a pipe was placed on the crown parallel to the axis of the barrel of the arch. A load was applied to this pipe by means of a plank resting on a knife-edge and holding a vessel on one end and a counterweight on the other. The knife-edge was off the scale and the load was applied by pouring water in the vessel, thus tipping the plank on to the arch. It was measured by weighing the added load on the scales. The deflections were taken at the crown with an Ames dial. In this arch the

angle of skew was  $22\frac{1}{2}^\circ$  and the breadth measured parallel to the abutments was 10 in. Fig. 7 shows the arch after failure. Note that the breaks are parallel to the axis of the barrel. The results of this run are given in Fig. 8.

#### COMPARISON WITH THEORY

The components of the crown reactions on a skew arch ring of the character of the models used have been determined for a vertical crown load using the elastic theory previously mentioned. This work is given in the Appendix. By taking the readings of the abutment dynamometers, as determined from Tables 1, 2, and 3, and from these, computing the stresses at the crown, a comparison can be made.

The crown reactions were computed from the following equations of equilibrium for the left half of the arch ring:

$$\left. \begin{aligned} T_x &= A + B \\ T_y &= D + E + F \\ T_z &= C \\ M_x &= c T_y - 7.15 F - e T_x \\ M_z &= 12.4 D - a T_y + d T_x \end{aligned} \right\} \dots\dots\dots (1)$$

in which,  $A, B, C, D, E$ , and  $F$  are the abutment dynamometer readings, and  $a$  = crown to plane,  $E F$ ;  $b$  = width of arch ring;  $c$  = crown to plane,  $D E$ ;  $d$  = elevation of crown above  $C$ ; and  $e$  = elevation of crown above plane,  $A B$ , as defined in Tables 1, 2, and 3. The values of the dynamometer readings were taken from the slopes of the lines as plotted from these tables.

Fig. 9 was plotted from Table 1. A 50-lb. increase in the crown load would produce the following increases in the abutment dynamometer readings:  $A = 26.5$  lb.;  $B = 15.5$  lb.;  $C = 19.5$  lb.;  $D = 10.3$  lb.;  $E = 21.3$  lb.;  $F = -3.3$  lb.; which with the following measurements:  $a = 11.125$  in.;  $c = 15.00$  in.;  $d = 8.31$  in.; and  $e = 8.16$  in., substituted in Equation (1), give  $T_x = 42.0$  lb.;  $T_y = 27.3$  lb.;  $T_z = 19.5$  lb.;  $M_x = -21.7$  lb.; and  $M_z = 85.8$  lb.

The theoretical values are:  $T_x = 40.4$  lb.;  $T_y = 25.0$  lb.;  $T_z = 15.7$  lb.;  $M_x = -18.1$  lb.; and  $M_z = 61.2$  lb.

Fig. 10 was plotted from Table 2. A distinct break occurs in the curves at the 30.5-lb. load, where Dynamometer  $F$  ran to zero and it became necessary to place a weight on the trough where it was attached to this dynamometer.

From the lower part of the curves for a 50-lb. increase:  $A = 12.4$  lb.;  $B = 25.9$  lb.;  $C = 21.0$  lb.;  $D = 13.5$  lb.;  $E = 18.2$  lb.; and  $F = -7.9$  lb.

With  $a = 16.6$  in.;  $c = 14.85$  in.;  $d = 9.5$  in.; and  $e = 9.34$  in., Equations (1) gives,  $T_x = 38.3$  lb.;  $T_y = 23.8$  lb.;  $T_z = 21.0$  lb.;  $M_x = -28.2$  lb.; and  $M_z = 51.2$  lb.

From the upper part of the curves for a 50-lb. increase:  $A = 17.2$  lb.;  $B = 22.3$  lb.;  $C = 26.0$  lb.;  $D = 11.4$  lb.;  $E = 21.5$  lb.; and  $F = -7.5$  lb.; which gives as values for the crown forces and moments:  $T_x = 39.5$  lb.;  $T_y = 25.4$  lb.;  $T_z = 26.0$  lb.;  $M_x = -33.3$  lb.; and  $M_z = 65.3$  lb.

The theoretical values are:  $T_x = 40.6$  lb.;  $T_y = 25.0$  lb.;  $T_z = 23.8$  lb.;  $M_x = -34.6$  lb.; and  $M_z = 60.8$  lb.

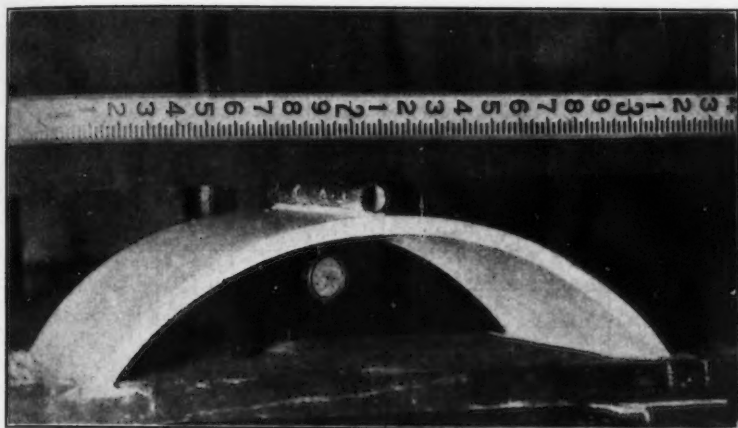

FIG. 6.—TEST ON UNLOADED ARCH.

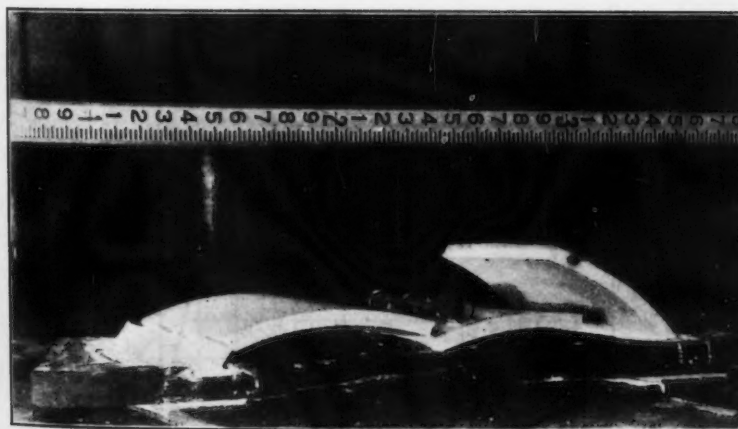

FIG. 7.—VIEW OF ARCH AFTER FAILURE.

Fig. 11 was plotted from Table 3. A 50-lb. increase in the crown load would produce the following:  $A = 16.0$  lb.;  $B = 27.2$  lb.;  $C = 27.6$  lb.;  $D = 15.0$  lb.;  $E = 16.2$  lb.; and  $F = -2.4$  lb. With  $a = 17.0$  in.;  $c = 15.1$  in.;  $d = 9.26$  in.; and  $e = 9.1$  in., Equations (1) gives:  $T_x = 43.2$  lb.;  $T_y = 28.8$  lb.;  $T_z = 27.6$  lb.;  $M_x = -48.0$  lb.; and  $M_z = 58.9$  lb.

The theoretical values are:  $T_x = 40.8$  lb.;  $T_y = 25.0$  lb.;  $T_z = 31.0$  lb.;  $M_x = -43.3$  lb.; and  $M_z = 59.8$  lb.

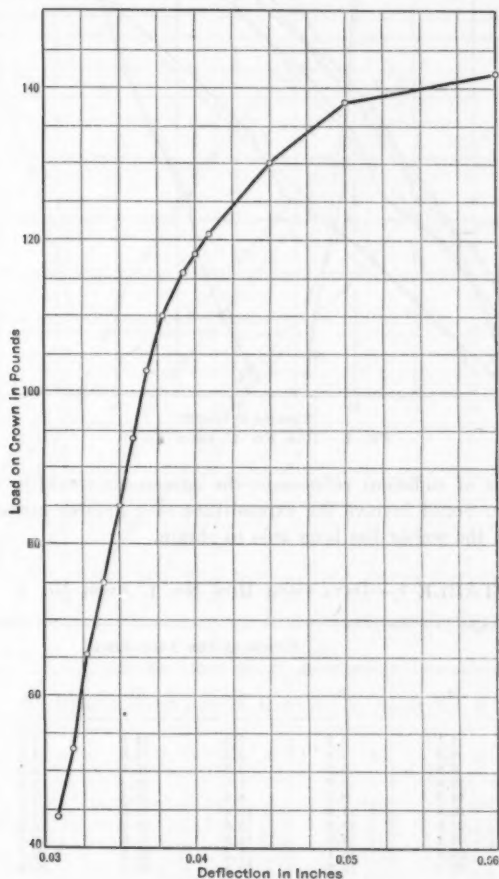

FIG. 8.—PRELIMINARY RUN.

Although the agreement of the theoretical and the observed values is not as close as could be desired, considering the many sources of error in the experiments, it is close enough to convince one that the theory is a reliable method of obtaining stresses in a skew arch ring, and the writer feels that

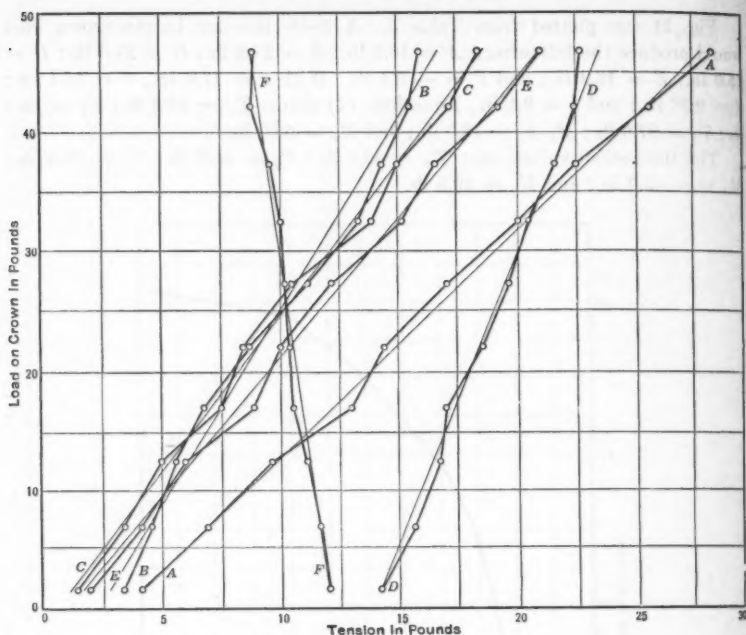

FIG. 9.—RUN NO. 1, ARCH NO. 1.

with apparatus of sufficient refinement the agreement would be closer. This work, however, would involve the expenditure of a greater amount of money and time than the writer has been able to obtain.

TABLE 1.—DATA FROM RUN NO. 1, ARCH NO. 1.

#### EFFECT OF THE ABUTMENT MOVEMENTS

The abutment of the arch with a  $31^\circ$  skew was moved in a horizontal direction without rotation parallel to the axis of the barrel of the arch, in order to

test the effect on the abutment reactions of such a movement. Unfortunately, no readings were taken to ascertain the amount of this movement. Needles Nos. 1 and 2 were kept in position while the pointer of Needle No. 3 was moved horizontally by varying the load on the dynamometers. Rotation of the abutments was also prevented. From Table 4 and Fig. 12 the tendency can be easily noted. As Dynamometer *C* was released in order to keep the span of the arch a constant, Dynamometer *B* received load from Dynamometer *A*, while Dynamometer *D* received load from Dynamometers *E* and *F*.

NOTE.— $\alpha = 17.00$  in.;  $b = 9$  in.;  $c = 15.10$  in.;  $d = 9.26$  in.;  $e = 9.10$  in.; and angle of skew = 37 degrees.

A third arch was put in the testing frame and a load of about 30 lb. was placed on the arch crown. This arch had an angle of skew of  $37^\circ$  and a length of abutment of 9 in. The abutment was moved parallel to itself without rotation and in a direction to widen the span, horizontally but at right angles to the barrel of the arch. Table 4 and Fig. 12 give the effect of this movement. This is a possible direction in which the arch may slip under load. It is interesting to note that the horizontal force, *B*, becomes zero, or that the abutment force is very near the point of the arch. Table 5 is produced by a movement similar to the one producing Table 3; that is, parallel to the axis of the barrel of the arch. It is interesting to compare the results of these two movements.

## CONCLUSIONS

Although the apparatus for recording abutment movements could be improved a great deal by being made lighter and a method could be devised for controlling the pressure on the needles, it is the writer's opinion that the following conclusions are warranted:

(1) If the abutment moves in a known direction and amount, the stresses are redistributed in a manner that can be foreseen from the elastic theory.\* They may cause the heavier load on one or the other end of the abutment, depending on the direction of slipping.

(2) The force represented by  $T_z$ , or Dynamometer  $C$ , must be provided for in the design of a skew arch ring.

(3) The obtuse corner of the abutment does not necessarily carry any heavier load than the acute corner, and may carry less.

(4) The discrepancies between the values obtained by the arch theory and those obtained by experimentation are within the range of experimental error so that this set of experiments supports the theory.

## ACKNOWLEDGMENT

Appreciation is extended to C. E. Magnusson, M. Am. Soc. C. E., for obtaining funds from the University of Washington Experiment Station with which to make the necessary apparatus and models to conduct these tests; and, also, to W. R. Engstrom, Jun. Am. Soc. C. E., for obtaining a large percentage of the data herein given.

## APPENDIX

The theoretical values for the crown reactions for a concentrated vertical central load are given by solving the following six equations:†

$$\begin{aligned} & \left( \int y^2 \frac{ds}{I_z} + \epsilon^2 \lambda \int x^2 \sin^2 \phi \frac{ds}{F} \right) T_z - \left( \epsilon \lambda \int u x \sin \phi \frac{ds}{F} \right) T_x \\ & + \left( \int y \frac{ds}{I_z} \right) M_z - \left( \epsilon \lambda \int x \sin \phi \cos \phi \frac{ds}{F} \right) M_x \\ & = \frac{1}{2} \int x y \frac{ds}{I_z} W + \frac{1}{2} \epsilon^2 \lambda \int x^2 \sin \phi \cos \phi \frac{ds}{F} W \dots\dots (2a) \end{aligned}$$

$$\begin{aligned} & \left( \int x^2 \frac{ds}{I_z} + \epsilon^2 \lambda \int x^2 \cos^2 \phi \frac{ds}{F} \right) T_v - \left( \epsilon \lambda \int x \sin \phi \cos \phi \frac{ds}{F} \right) M_v \\ & = -\frac{1}{2} \int x^2 \frac{ds}{I_z} W - \frac{1}{2} \epsilon^2 \lambda \int x^2 \cos^2 \phi \frac{ds}{F} W \dots\dots (2b) \end{aligned}$$

$$\begin{aligned} & \left( -\epsilon \lambda \int u x \sin \phi \frac{ds}{F} \right) T_x + \left( \lambda \int u^2 \frac{ds}{F} \right) T_z + \left( \lambda \int u \cos \phi \frac{ds}{F} \right) M_x \\ & = -\frac{1}{2} \epsilon \lambda \int u x \cos \phi \frac{ds}{F} W \dots\dots\dots (2c) \end{aligned}$$

$$\left( \int y \frac{ds}{I_z} \right) T_x + \left( \int \frac{ds}{I_z} \right) M_z = \frac{1}{2} \int x \frac{ds}{I_z} W \dots\dots\dots (2d)$$

\* Compare the results of Tables 4 and 5 with the statements in *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p. 675.

† *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), pp. 617-618 and pp. 642-644.

$$\begin{aligned} & \left( -\varepsilon \lambda \int x \sin \phi \cos \phi \frac{ds}{F} \right) T_y + \left( \lambda \int \sin^2 \phi \frac{ds}{F} \right) M_y \\ & = \frac{1}{2} \varepsilon \lambda \int x \sin \phi \cos \phi \frac{ds}{F} W \dots \dots \dots (2e) \end{aligned}$$

$$\begin{aligned} & \left( -\varepsilon \lambda \int x \sin \phi \cos \phi \frac{ds}{F} \right) T_z + \left( \lambda \int u \cos \phi \frac{ds}{F} \right) T_z \\ & + \left( \lambda \int \cos^2 \phi \frac{ds}{F} \right) M_z = -\frac{1}{2} \varepsilon \lambda \int x \cos^2 \phi \frac{ds}{F} W \dots \dots (2f) \end{aligned}$$

The solution of Equations (2b) and (2e) is obviously  $T_y = -\frac{1}{2}$  and  $M_y = 0$ , and no further consideration of these equations is necessary.

As the arch consists of the segment of a circular cylinder, from the properties of a circle the following substitutions may be made:

$$\begin{aligned} x &= r \sin \phi \\ y &= r (1 - \cos \phi) \\ u &= y = r (1 - \cos \phi) \\ v &= x = r \sin \phi \end{aligned}$$

$$\frac{ds}{r} = d\phi$$

$$\frac{1}{I_x} = \frac{12}{b d^3} = 4 \times \frac{3}{b d^3}$$

$$\frac{\lambda}{F} = \frac{9}{b d^3} = 3 \times \frac{3}{b d^3}$$

$b$  = width of arch ring.

$d$  = thickness of arch ring.

After dividing through by the common term,  $\frac{3 r^2}{b d^3}$ , or  $\frac{3 r}{b d^3}$ , this reduces the equations to:

$$\begin{aligned} & \left( 4 \int (1 - \cos \phi)^2 d\phi + 3 \varepsilon^2 \int \sin^4 \phi d\phi \right) r T_x \\ & - \left( 3 \varepsilon \int (1 - \cos \phi) \sin^2 \phi d\phi \right) r T_z + \left( 4 \int (1 - \cos \phi) d\phi \right) M_z \\ & - \left( 3 \varepsilon \int \sin^2 \phi \cos \phi d\phi \right) M_z = 2 r \int (1 - \cos \phi) \sin \phi d\phi \\ & + \frac{3}{2} \varepsilon^2 r \int \sin^3 \phi \cos \phi d\phi \dots \dots \dots (3a) \end{aligned}$$

$$\begin{aligned} & \left( -3 \varepsilon \int (1 - \cos \phi) \sin^2 \phi d\phi \right) r T_x + \left( 3 \int (1 - \cos \phi)^2 d\phi \right) r T_z \\ & + \left( 3 \int (1 - \cos \phi) \cos \phi d\phi \right) M_z \\ & = -\frac{3}{2} \varepsilon r \int (1 - \cos \phi) \sin \phi \cos \phi d\phi \dots \dots \dots (3c) \end{aligned}$$

$$\left( 4 \int (1 - \cos \phi) d\phi \right) r T_z + \left( 4 \int d\phi \right) M_z = 2 r \int \sin \phi d\phi \dots (3d)$$

$$\begin{aligned} & \left( -3 \varepsilon \int \sin^2 \phi \cos \phi d\phi \right) r T_x + \left( 3 \int (1 - \cos \phi) \cos \phi d\phi \right) r T_z \\ & + \left( 3 \int \cos^2 \phi d\phi \right) M_z = -\frac{3}{2} \varepsilon r \int \sin \phi \cos^2 \phi d\phi \dots \dots (3f) \end{aligned}$$

Integrating and substituting the limits of  $\frac{\pi}{3}$  and 0, and reducing terms:

$$\left(\frac{4\pi}{3} - 4\sqrt{3} + \frac{\sqrt{3}}{2} + \frac{2\pi}{3} - \frac{9\sqrt{3}}{64}\epsilon^2 - \frac{9\sqrt{3}}{32}\epsilon^2 + \frac{3\pi}{8}\epsilon^2\right)rT_x \\ + \left(\frac{3\sqrt{3}}{8}\epsilon - \frac{\pi}{2}\epsilon + \frac{3\sqrt{3}}{8}\epsilon\right)rT_z + \left(\frac{4\pi}{3} - \frac{4\sqrt{3}}{2}\right)M_x \\ - \left(\frac{3\sqrt{3}}{8}\right)\epsilon M_x = -\left(2r + \frac{3}{2}r - \frac{27}{64}\epsilon^2 r - 4r\right)\frac{1}{2} \dots (4a)$$

$$\left(\frac{3\sqrt{3}}{8} - \frac{\pi}{2}\epsilon + \frac{3\sqrt{3}}{8}\epsilon\right)rT_x + \left(\pi - 3\sqrt{3} + \frac{3\sqrt{3}}{8} + \frac{\pi}{2}\right)rT_z \\ + \left(\frac{3\sqrt{3}}{2} - \frac{3\sqrt{3}}{8} - \frac{\pi}{2}\right)M_x = -\left(\frac{9}{8}\epsilon r + \frac{1}{8}\epsilon r - \epsilon r\right)\frac{1}{2} \dots (4c)$$

$$\left(\frac{4\pi}{3} - 2\sqrt{3}\right)rT_x + \frac{4\pi}{3}M_x = (-2r + 4r)\frac{1}{2} \dots (4d)$$

$$\left(-\frac{3\sqrt{3}}{8}\right)\epsilon rT_x + \left(\frac{3\sqrt{3}}{2} - \frac{3\sqrt{3}}{8} - \frac{\pi}{2}\right)rT_z + \left(\frac{3\sqrt{3}}{8} + \frac{\pi}{2}\right)M_x \\ = \left(\frac{1}{8}\epsilon r - \epsilon r\right)\frac{1}{2} \dots (4f)$$

Substituting the numerical values, these equations reduce to:

$$(0.2210 + 0.4474\epsilon^2)rT_x - 0.2718\epsilon rT_z + 0.7247M_x - 0.6495\epsilon M_x \\ = (0.2500 + 0.2110\epsilon^2)r \dots (5a)$$

$$-0.2718\epsilon rT_x + 0.1658rT_z + 0.3777M_x = -0.1250\epsilon r \dots (5c)$$

$$0.7247rT_x + 4.1888M_x = 1.0000r \dots (5d)$$

$$-0.6495\epsilon rT_x + 0.3777rT_z + 2.2203M_x = -0.4375\epsilon r \dots (5f)$$

the solutions of which are:

$$2T_x = \frac{2.0217 + 0.0689\epsilon^2}{1.2550 + 0.0148\epsilon^2} \\ 2T_z = \frac{1.9620 + 0.0948\epsilon^2}{1.2550 + 0.0148\epsilon^2}\epsilon \\ 2M_x = \frac{-0.2340 - 0.0017\epsilon^2}{1.2550 + 0.0148\epsilon^2}\epsilon r \\ 2M_z = \frac{0.2495 - 0.0048\epsilon^2}{1.2550 + 0.0148\epsilon^2}r$$

TABLE 6.—ARCH DATA FOR  $r = 12\frac{3}{4}$  INCHES.

Skew angle.	22°	31°	37°
$\epsilon$ .....	0.404	0.600	0.754
$T_x$ .....	0.808	0.812	0.816

With  $r = 12\frac{3}{4}$  in., these values, for a unit central load, are as given in Table 6.

## DISCUSSION

B. F. JAKOBSEN,\* M. Am. Soc. C. E. (by letter).—The writer is interested in arches as applied to dams and has studied Professor Rathbun's paper with great interest. Bearing in mind the complicated stress distribution in the structure and the relatively simple testing apparatus, the agreement between the experimental values and the calculated values based on Professor Rathbun's theory,† seems very good; especially when account is taken of the fact that in order to simplify the mathematics some approximations must be made in the assumptions, and that the measurements are not exact.

Assuming that the mathematical deductions are correct, the tests show that the fundamental assumptions made by Professor Rathbun lead to reliable results. The way is now open for the advocates of "horse sense"‡ to test their "theories" and submit the results to the profession. These theories, based on "horse sense," are likely to have the advantage of simplicity and the disadvantage of being incorrect, as may be inferred from the number of failures recorded.§ An exact theory cannot be obtained for the reason that the modulus of elasticity is not the same for all parts of the structure and varies with time; the deformations continue to increase with time even when the load is constant,|| temperatures vary, etc.

The development of a useful theory depends largely on the ability and skill of the scientist to distinguish the essential from the unimportant and to formulate such assumptions as will lead to reliable results without undue mathematical complications.

The writer is especially interested in Fig. 8 because it shows the great and rapidly increasing deflection of the arch as the breaking load is approached. When the load was increased from zero to about 102 lb., the arch deflected about 0.01 in., while, when the load was increased from 102 lb. to 142 lb. (the breaking load), the additional deflection was 0.023 in. This means that, in the sections subjected to bending stresses, the neutral axis was shifted toward the compression side and the section was able to carry a much larger bending moment than calculations based on the tensile strength of the material would indicate.

Professor Bach¶ has made tests on cast iron in bending and, at the same time, has tested the cast iron in tension and compression in order to obtain the stress-strain curve. By this means he found that the bending moment necessary to bring about failure was about 1.66 times greater than the theoretical bending moment based on the tensile strength of the cast iron. He was also able to calculate the distance which the neutral axis moved from its theoretical position through the center of gravity of the section.

¶ "Elasticität und Festigkeit," Ninth Edition, p. 298; see, also, Figs. 18 and 19 of the writer's paper, "Stresses in Thick Arches of Dams," Transactions, Am. Soc. C. E., Vol. 90 (1927), p. 508.

Bending tests on plain concrete beams have shown that the bending moment necessary to bring about failure is about twice that computed from the tensile strength of the concrete. This must be due to a shifting of the neutral axis, as was found for cast iron. The same phenomenon must make itself felt also when tension is not present; that is, when the resultant lies within the middle third of the section. This would mean that the structures have considerably greater strength than calculations with a constant modulus of elasticity would indicate, and that added strength has undoubtedly saved a number of poorly designed structures. Therefore, the fact that a structure which, according to theory, ought to fail and yet does not fail, does not mean that the theory is not to be relied on, but rather that the ordinary theory errs somewhat on the side of safety. This is a fortunate circumstance for engineers; it means that structures have, so to speak, a certain over-load capacity.

Professor Rathbun's tests should help to give confidence in theories based on the fundamental assumptions. He has performed a real service.

EDWARD GODFREY,\* M. AM. SOC. C. E. (by letter).—Structural engineering in its proper functioning consists, not in working out a theoretical problem, but in building a structure that cannot be assailed from the standpoint of other theory, even if that theory appears to be of a lower grade and to savor of practical knowledge.

The writer is in agreement with George F. Swain, Past-President and Hon. M. Am. Soc. C. E.,† both in questioning the correctness of applying the elastic theory to concrete or reinforced concrete arches and in considering a skew arch as anything but an unsymmetrical arch subject to twisting stresses. Professor Swain gives some very sound reasons why the elastic theory is inappropriate for the solution of reinforced concrete arch problems. The extremely complex theoretical treatment of this subject should be eliminated and the "row-of-blocks" method, which is frankly an approximation and not camouflaged with meaningless and misleading mathematics, should be substituted.

Professor Swain states very aptly, "Nobody can ever know which method is the more accurate, but he should realize that more mathematics does not mean more accuracy". If the question were merely one of arriving at two nearly identical results by different paths, there would be no reason to object to any engineer's selection of the difficult mathematical path; but the objection which the writer urges against the elastic theory for a thing that can be proved not to be elastic is that a weaker structure undoubtedly is the result.

The one serious count against the elastic theory for reinforced concrete arches is that it assumes absolute rigidity in the abutments. This generally means that the design of the abutments is given no consideration whatever. The writer does not recall a single instance where a proponent of the elastic theory for arches considers the possibility of abutments not being absolutely, or even approximately, rigid. Furthermore, although replies to arguments against the elastic theory on the grounds of rotating, sinking, or shifting abutments state that this movement must be theoretically treated, no hint is given as to how the amount of rocking or shifting is to be determined.

\* Structural Engr., Pittsburgh, Pa.

† "Stresses, Graphical Statics, and Masonry."

Another basic assumption in the elastic theory is that the concrete is elastic. This is almost as serious an error as to assume fixed ends. To state that a thing is elastic from an engineering standpoint does not mean merely that it will return to its original shape after being stressed and the load removed. There are any number of heterogeneous combinations of springy materials, that could be made to fill this definition. To be elastic in the engineering, mathematical sense can only mean one thing, and that is that every part of the member so considered is not only elastic in the ordinary sense, but has the same modulus of elasticity. It is well known that concrete is far from fulfilling this condition. The modulus of elasticity of concrete is not constant. One mixture of given materials may have one value and another mixture of the same materials may have a value differing from the first by 50 to 100 per cent. The entire theoretical treatment of the arch is based on this value being constant, and no opinion can eliminate the bald fact that the whole treatment is so much waste effort if the modulus of elasticity is not even approximately constant. The elastic theory further assumes an original unstressed condition of the arch. This means that, if the arch could be submerged in a fluid of exactly its own specific gravity, it would assume precisely the shape that would fit its abutments. It is doubtful whether any one believes that shrinkage and expansion of concrete do not tend to distort any arch that can be built.

Professor Rathbun's tests proved the variability of the modulus of elasticity of plaster of Paris due to the use of varying quantities of water. Cement being, like plaster of Paris, a colloidal substance, will give a product varying in the same way. The argument that modern concrete is an exact product does not require a man to be on a field job more than one day to answer in the negative.

There is still another sense in which concrete is not elastic. Experiments have shown that, when subject to long-time tests, it takes a permanent set. This is a fact that need give little concern in an arch designed on the non-elastic basis with its liberal depth of arch ring. In fact this will tend to equalize the stresses. However, in the thin, reinforced concrete arch ring, designed on the elastic theory with part of the cross-section possibly in tension, a permanent set is apt to be serious.

Professor Rathbun's tests on skew arches seem to confirm his theory set forth in his earlier paper,\* and they agree with that of Rankine for skew arches. Theoretically, such arches act as right arches; not showing, as many believe, a tendency for the load to take the short course to the abutments and overload the obtuse corners of such abutments. It is to be noted that in these tests extensive provisions were necessary to maintain fixed abutments. It is also to be noted that, when the abutments were allowed to shift only a little, the tendency to overload the obtuse corners was very manifest; that is, the reaction went to the obtuse corner. It is exactly this tendency that makes the skew arch, built as such, a menace.

\* "Analysis of the Stresses in the Ring of a Concrete Skew Arch," *Transactions, Am. Soc. C. E.*, Vol. LXXXVII (1924), p. 611.

In a laboratory on a small model it is possible to maintain rigid or fixed abutments. In a bridge, this is not a possibility. Tests on a full-sized arch bridge\* (119 ft. span) have proved that rotation of the piers is perceptible although the piers are founded on rock. This recent light on the action of concrete arches and the instability of their abutments is of tremendous significance. If a pier founded on rock rotates, what would happen where the foundation is ordinary soil, and how is any complex theory, that makes for the absolute minimum thickness in an arch ring on the assumption of perfect fixedness of abutments, going to justify its existence?

Professor Rathbun's model test shows that a small endwise movement of a pier in the skew arch affects the distribution of the thrusts, throwing the main thrust into the obtuse corners of the abutments. In a bridge there will be a very heavy component of the thrust on the pier tending to move it in exactly that way. To take this thrust, there would have to be constructed special thrust-bearings, and these would have to bear against vertical surfaces of earth, which offer but uncertain resistance. Professor Rathbun recognizes the need of this provision in his Conclusion (2), but it is to be noted that in his tests it was taken care of by adjustment. No adjustment is possible in a concrete structure, and settlement is always one of the things to be expected. A settlement against a horizontal surface of earth in response to an active horizontal force is certain and unavoidable. Such settlement means that the reactions assumed in the design are not realized and that all the design calculations are in error.

The writer is in agreement with Professor Rathbun's† earlier ideas on the subject of skew arches, expressed in a letter in which, in commenting on the failure of a skew arch at Tacoma, Wash., he states:

"By means of models it has been repeatedly shown that the thrust is greater at the obtuse corner [in plan] than at the acute. \* \* \* Waddell, in 'De Pontibus', says, 'A skew bridge is a structure the building of which should always be avoided when it is practicable'. After a great deal of study on the theory of the skew arch the writer has come to the conclusion that Waddell was right, even if the remark was written before the days of reinforced concrete".

Clyde T. Morris, M. Am. Soc. C. E., has stated‡ that tests on a skew arch in a laboratory show that the greater part of the reaction is close to the obtuse corner. In some cases the reaction at the acute corner is negative. Hool§ states that,

"Skew arches may be treated exactly as right arches, the span being taken parallel to the center line of the roadway and not at right angles to the springing lines of the arch".

It is this idea which Professor Rathbun's tests and comments foster, but which practical considerations show to be dangerous. The writer is of the

‡ *Loc. cit.*, April 20, 1922, p. 638.

§ "Reinforced Concrete Construction," Vol. III, p. 43.

opinion that, if a skew arch must be used, it should be done by constructing separate parallel ribs not bonded in such manner as to transmit shear from one to another.

The Bendigo Arch, a skew structure that failed,\* had especially massive foundations built on solid rock. The materials were excellent. However, the arch failed by crushing the abutments at the obtuse corners.

J. CHARLES RATHBUN,† M. Am. Soc. C. E. (by letter).—The experiment described in this paper was performed to test the validity of the assumptions made in developing the theory of the skew arch.‡ Subsequently, George E. Beggs, M. Am. Soc. C. E., conducted a far more elaborate set of experiments, using several arches of varying proportions. The writer compared the data from this set with the results deduced from his equations and found the comparison far more favorable than those described in the paper. Influence surfaces were reproduced to show the comparison for the entire set.

By making computations for varying values of  $F$  for an arch with dimensions otherwise the same, it has been found that little change in the results is produced if the variation is not greater than 20 per cent. In this case, the quantity,  $\frac{\lambda}{F}$ , was given values 20% greater and 20% smaller. If an extreme change is made the results are affected very materially. These computations were made to test the validity of the objections sometimes raised that the accuracy of the whole theory rests on that of the formula used for the value,  $F$ , which may not apply to a rectangle as slender as those used in arch design. The writer doubts very much if it is 20% in error.

A comparison of Mr. Godfrey's discussion with that of Mr. Jakobsen is very interesting, giving as it does the pro and con of scientific design *versus* "horse-sense" methods. The many catch problems that abound in engineering usually yield to a careful analysis, giving results that are different from the solution that at first appears obvious from the "horse-sense" method of attack. The skew arch is one of these problems. Although many engineers have advocated the idea that the obtuse corner carries the load, none of them has given a quantitative solution, so that designers can have a basis on which to compute stresses and earth pressures.

Mr. Godfrey emphasizes the fact that the abutments may not be rigid. The effect of abutment movement has been previously stated by the writer§ as follows:

"The theory as developed implies rigid abutments. A positive movement of the abutment in the direction,  $Z$ , causes the line of force to shift toward the obtuse corner, that is, to tend to follow the shortest route to the abutment. A similar movement in the direction,  $X$ , however, will cause it to shift away from the obtuse corner. Rotation about a  $z$ -axis will cause a similar shifting either toward or away from the obtuse corner, depending on the direction of rotation."

§ *Loc. cit.*, p. 675.

If the tangent of the angle of skew is somewhat less than unity the thrust in the direction,  $Z$ , is less than that in the direction,  $X$ . The tendency to move in the direction,  $X$ , is, therefore, greater than in the direction,  $Z$ , and the effect of the abutment movement would be opposite to that indicated by Mr. Godfrey. As the paragraph quoted was a very important one, it was verified experimentally.

Mr. Godfrey calls attention to the fact that the writer, before conducting experiments, and deducing the equations published in 1924, had fallen into the error still advocated as "horse sense". This is clearly a point in favor of the theory, as the experimenter was not trying to prove and publish a pet theory or, if he was, he was forced to conclude that he was in error after seeing the results of experiment and computations from the mathematical equations. It is hoped that the others who have committed themselves on this problem will admit that mathematical and experimental research have more weight than their first "snap" judgment.

Paper No. 1726

### FLOOD CONTROL ON THE RIVER PO IN ITALY\*

BY JOHN R. FREEMAN,† PAST-PRESIDENT, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. MCD. TOWNSEND, OREN REED, JOHN P. HOGAN, WILLIAM B. GREGORY, JOHN R. SLATTERY, ARTHUR P. DAVIS, G. DE THIERRY, M. GIANDOTTI, R. D. GOODRICH, C. E. GRUNSKY, AND JOHN R. FREEMAN.

#### SYNOPSIS

1.—This paper reports observations made by the writer on a tour in September, 1927.

2.—The Po is by far the most important river in Italy, drains one-third of its area, and flows through a broad valley rich in agriculture.

3.—The story published many times in the course of discussions on the control of the Mississippi River, that the bed of the River Po has been raised by deposit of sediment to elevations above that of the adjacent country, is found untrue.

It is true that there has been an increase in the elevation to which great floods have risen. Perhaps this is due to confining the waters within narrower limits and to the building up of deposits of sediment on the land between the main dikes and the river channel.

4.—Following the greatest flood of record, in 1926, works are now planned for raising the main dikes 3.3 ft. for many miles along the lower river.

The deposit of sediment brought down by the River Po, and precipitated where the fresh water meets salt water, has extended its delta 15 or 20 miles within the historic period, thus increasing the length of the river and adding about 160 acres of marsh land each year. A century ago the average was nearly 530 acres per year. This material comes chiefly from erosion of the slopes of the Apennines.

5.—The drainage area of the Po receives an average rainfall of 42 in. per year, varying from 120 in. on some of the elevated mountain slopes to only

\* Presented at the meeting of June 6, 1928.

† Cons. Hydr. Engr., Providence, R. I.

20 in. in the low broad central valley, which has an average width of 40 miles for the lower 175 miles.

6.—Great floods along the Po have occurred from time immemorial and the river and its torrential tributaries have long been diked for protection.

7.—Hydraulic science was born in the valley of the Po, hundreds of years ago, and its earliest treatises relate to the control of its floods and its torrents. Leonardo da Vinci, Galileo, Torricelli, Guillimini, Frisi, and many others of the most eminent scientists of one to four centuries ago, gave great attention to its problems.

8.—Breaks in the dikes in the great flood of 1917, and the desire for increased facilities for navigation led to a remarkably complete collection of hydrographic data. The number of rain gauges in this drainage area was increased to nearly 1000, an average of 1 to each 30 sq. miles; river discharge gauging stations to 66, including 1 or more on each more important tributary; and 123 stations were established for frequent measurement of ground-water elevation within the broad valley.

These stations provide the foundation for what perhaps is the most intense study of a problem in river hydraulics ever undertaken anywhere in the world.

9.—Vast areas of land that are slightly below sea level, including marshes and beds of old lagoons, have been reclaimed by dikes and pumping. The cause of their being below sea level doubtless is a slow earth tilt or subsidence of the land around the Adriatic that has been observed for several centuries.

10.—The main lessons from the Po which seem applicable to Mississippi and Missouri River problems, are:

(a) The use of double lines of dikes (or network of dikes) which presents a second line of defense when the main dike is breached.

(b) The maintenance of large brick storehouses at intervals of 3 to 5 miles, in which hundreds of thousands of sacks, such as grain sacks, are stored in readiness for emergencies of building sand-bag coffer-dams.

(c) The organization of the inhabitants so that thousands of men can be quickly mobilized in case of danger.

(d) A system of flood forecasts, and telegraphic warning of floods, with careful estimates of height that probably will be reached at important points all along the river.

(e) The prevention of "cross-over" sand-bars, at points of change of direction of curvature between the bends, by narrowing the river at these points. On the Mississippi these bars are chiefly caused by the extra width at points of contraflexure and consequent slower velocity during flood. By deposits due to this action the flood obstructs its own discharge and rises to greater heights.

(f) The effort to minimize cost of dredging by training the river into a single, relatively narrow, channel.

(g) The minimizing of expenditure for revetment where funds are scarce by trying to retain the river in the channel in which it has for a time appeared to be content, without attempting to shorten its course by short cuts across the bends.

(h) The present program of channel improvement on the Po is tentative and subject to revision. Some of the most eminent hydraul-

cians in Italy believe that a hydraulic laboratory would aid in improving methods. Plans for a research laboratory at Stra, larger than those developed for purposes of instruction at the near-by engineering schools, have been outlined; but funds have not been available for its construction.

(i) The work of improvement is in charge of civil (not military) engineers; with an *ex-college* professor in charge of the wonderfully elaborate preliminary hydrographic work. The whole organization reports to the Department of Public Works. Some of the most eminent engineers of Italy, consultants, construction specialists, and professors in engineering colleges, were called upon to formulate the procedure.

#### INTRODUCTION

Because of statements here and there in engineering literature and encyclopedias, important if true (found to be mostly untrue), that the bed of the River Po had been raised above the elevation of the adjacent lands because of its enclosure by dikes for flood control, and the consequent deposit within the river bed of sediment which otherwise would have been spread out over broad areas of flooded land, the writer has long been trying to learn more about flood conditions, dikes, sediments, and elevation of river bed along this remarkable river.

The Po (Fig. 1) is the largest river in Italy. It drains much of the southern slopes of the Alps and most of the northern slopes of the Apennines, and with its tributaries, flowing through the broad fertile plain of Lombardy—a valley filled to a nearly level floor by its sediments—has for a thousand years presented outstanding problems in river control. It was in this region that hydraulic science had its birth. It was on one of its tributaries near Milan that Leonardo da Vinci, genius of widest range in all history, practiced canal engineering and constructed the earliest chamber lock for navigation (Porte Vinciane).

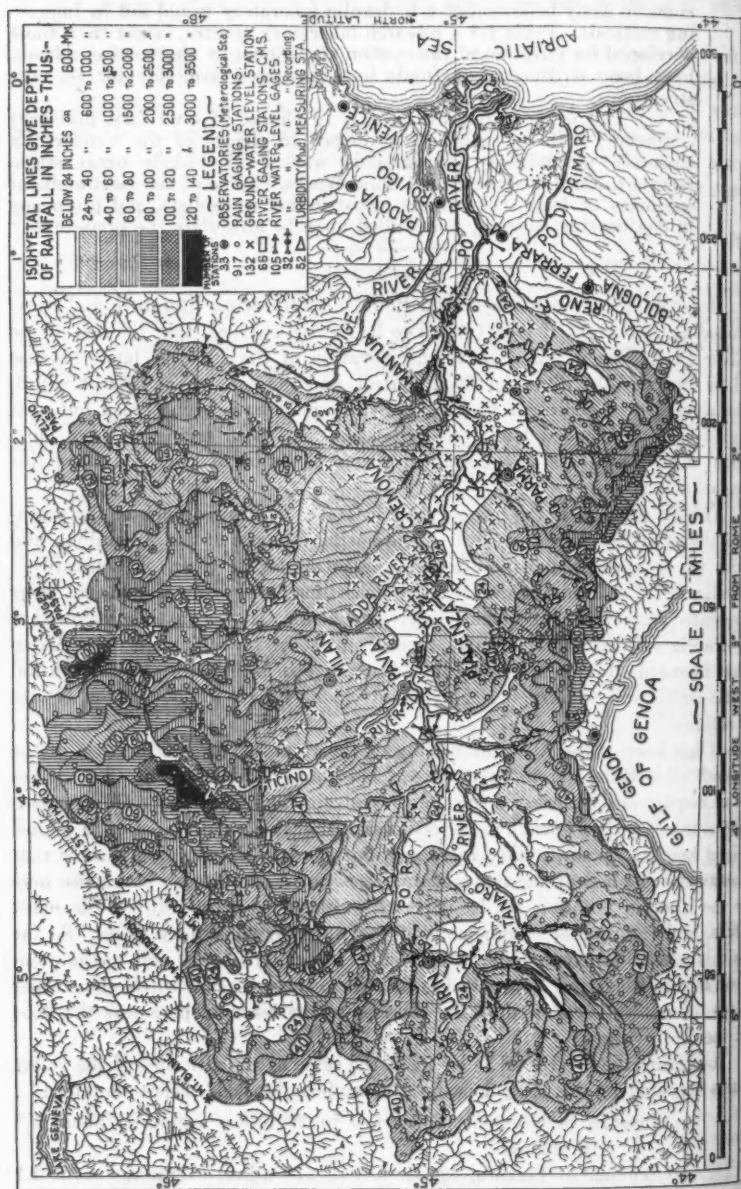

It has been stated that the raising of the river bed by the increase in the deposit of sediment from year to year, has compelled the height of the dikes to be continuously increased in order to restrain the higher floods from spreading over one of the world's most fertile and intensively cultivated delta plains. Flood heights certainly have increased, but the best data available show that meanwhile the bed of the main channel has not been raised. The cause may be the gradual building up, by deposits, of the flood-plain between the main dikes, and the greater confinement of the water by subsidiary dikes. So far as this condition exists, it pertains to the steeper tributaries and to the adjacent Rivers Reno and Adige, and is limited to those reaches where the steeper slope of valleys between the hills changes to the lesser slope across the floor of the main valley.

Assuming the flood level to be about the same as the altitudes of the valley cities reported in the *Encyclopædia Britannica*, the flood slopes would be:

Piacenza to Cremona, 62-ft. fall in 29 miles, averaging about 2.1 ft. per mile.

Cremona to Ferrara, 125-ft. fall in 110 miles, averaging about 1.1 ft. per mile.

Ferrara to the sea, 30 ft. fall in 50 miles, averaging about 0.6 ft. per mile.

Nearly all rivers decrease in declivity down stream, presenting a curved profile. Obviously, within the lower delta the slope must vary greatly with the river stage from flood to drought, because at 23 miles from the sea the flood surface is 20 ft. above its low-water elevation. This would give a flood slope of nearly 1 ft. per mile where the low-water slope is only about 0.10 ft. per mile.

An outstanding fact that may have had more or less effect on the downstream 200 miles of the main river, in raising both flood level and river bed, is that about 15 or 20 miles have been added to the length of the river since Roman times by the projection of its delta into the Adriatic through the deposit of sediment at its outlet, and that additional height or fall is required to carry the water over this added distance.

In the many controversies of 20 to 40 years ago, about adopting the levee system for the Mississippi, it was often stated (and also disputed) that confinement by dikes had raised the bed of the Po in Italy and of the Yellow River in China. The writer visited the Yellow River and had lines of levels run across its course at many places in the 240 miles between the crossing of the Peking-Hankow Railroad, and that of the Tientsin-Pukow Railroad, which proved those reports about the Yellow River to be mostly untrue, although not entirely so.\*

#### CONDITIONS PRESENTED ON THE PO

The total drainage area of the Po (Fig. 1) is about 28 000 sq. miles, or nearly one-third the area of all Italy. Its breadth from north to south averages nearly 100 miles. Its length from west to east in a straight line is only about 300 miles, although about 425 miles along the curving course of the river. Nearly one-fourth this nominal drainage area, or about 7 000 sq. miles, comprising the nearly level floor of the valley, which for its lower 1 750 miles averages 40 miles in width, does not drain directly into the river because of being enclosed by dikes which while keeping out the flood water that comes from up stream, hold the rain that falls on the surface inside the dikes. Much of the rain water soaks into the porous ground, some slowly escapes through drainage channels, and a large part goes skyward in evaporation.

The average annual rainfall for the entire area is 42 in., which is about the same as on New England rivers. On some of the high mountain slopes the total annual precipitation averages more than 100 in., while it averages only 24 in. on the broad valley floor. Data for the great flood of 1927 had not been published at the time of the writer's visit.

The three successive storms that caused the previous great flood of 1917, namely, June 3 to 10, of 1.97 in. depth of rainfall, June 19, of 2.68 in., June 28 to 31, of 5.36 in. (Fig. 2), an average total of 10.01 in. of rainfall on about 20 000 sq. miles within 28 days, would cause trouble almost anywhere.

The maximum run-off of about 300 000 cu. ft. per sec. in 1917 was about 11 cu. ft. per sec. per sq. mile if reckoned on the entire area; but if reckoned

\* "Flood Problems in China," by John R. Freeman, Past-President, Am. Soc. C. E., Transactions, Am. Soc. C. E., Vol. LXXXV (1922), p. 1422.

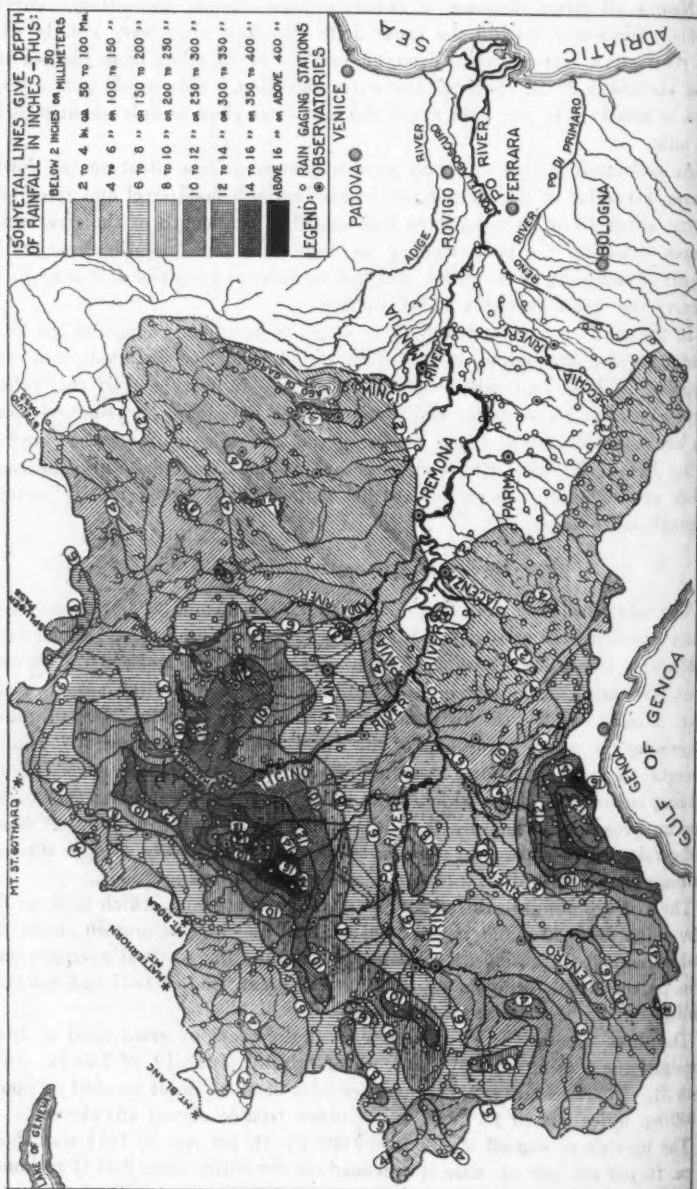

FIG. 2.—PO VALLEY, DISTRIBUTION OF RAINFALL, AVERAGING 5.36 INCHES FROM MAY 28 TO 31, 1917.

on the effective area, it was about 15 cu. ft. per sec. per sq. mile. This is equivalent to a depth of run-off of only 0.6 in. per 24 hours. This seems small for the record run-off of a century when one considers the depth of rainfall, the lay of the land, and the scant forest cover. Explanation may perhaps be found in an uncommonly absorptive soil, the surface of which at times of rain is never sealed by frost over any large proportion of the whole surface.

The northern edge of this water-shed is formed by the high Alps, rising from 1 mile to more than 2 miles above sea level; and its southern edge by the Apennines, some of the peaks of which are nearly a mile high.

The data given in Fig. 3 show a much more uniform distribution of rainfall and of run-off month by month than on most American drainage areas. The annual *Bulletin* of the Hydrographic Survey of the Po for 1923-24, published by the Department of Public Works, presents an admirably complete record, analyzed with great thoroughness. It forms a volume of two hundred and fifty, 10 by 14-in. pages, with large scale maps of the isohyets and many diagrams of discharge.

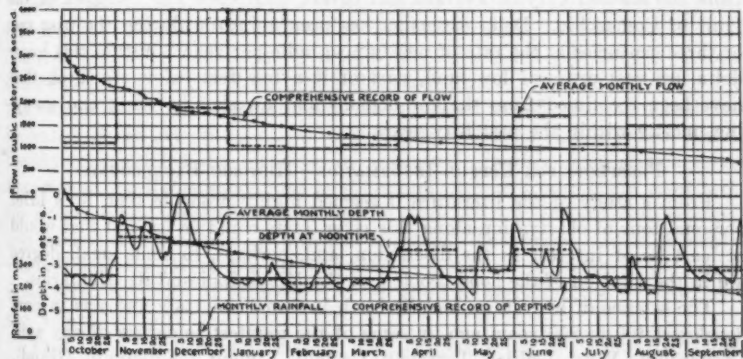

FIG. 3.—RELATION OF MONTHLY RAINFALL ON TOTAL WATER-SHED TO HEIGHT OF RIVER PO AT PONTELAGOSCURO, FOR HYDROLOGIC YEAR, 1923-24.

In brief, the deductions from the records of the 883 rain gauges in service for that year gave an average precipitation weighted according to areas adjacent to each gauge by mapping, of 1 085 mm., or 42.7 in., for 1923-24, and 982 mm., or 36.7 in., for the year next previous. On 68.5% of the drainage area it exceeded 1 200 mm., or 47 in., in 1923-24. In the six months—October to March—there was a total average precipitation of 496 mm., or 19.5 in.

The continuous gaugings of discharge at Pontelagoscuro indicate a total quantity of water equivalent to a sheet, 630 mm. (equal to 25 in.) in thickness over the entire drainage area, which, since the average precipitation was 1 085 mm., gives a run-off of 58% of the precipitation. For 1922-23, this ratio was 57%; for 1921-22, 52%; and for 1920-21, 68 per cent.

The turbidity measurements showed that during the year about 6 170 000 metric tons computed as dry silt passed the gauging station at Pontelagoscuro, which corresponds to an average erosion of 113 tons from each square kilometer of the drainage area, or equivalent to about 0.0029 in. in depth per year,

or  $\frac{1}{2}$  in. per century, from the entire drainage area; but, as stated elsewhere, most of this comes from the steep slopes of the Emilian Apennines.

The lay of the land in this great valley of the River Po presents conditions on all sides which one would expect to aggravate sudden floods—high mountains, moist air swept northward from the sea, steep declivities, short swift mountain currents—all bringing the rainfall rapidly from north, south, and west, into a broad and nearly level valley floor. This floor is roughly 150 miles long by 50 miles broad, and has been formed during hundreds of thousands of years by the sand and mud eroded from the mountain slopes and brought in by the currents, filling up a broad valley that doubtless once was deep and of V-shaped cross-section, but which now presents a relatively small declivity for drainage toward the sea. Within this present broad and nearly level plain, the main river and its many tributary rivers are confined by dikes from overflowing the highly cultivated land.

That part of the delta formed within the past 2 000 years, comprising about 750 sq. miles, or nearly 3% of the entire drainage area, lies down stream from the ancient City of Ferrara and covers what once was the apex of the Gulf of Comacchio. Delta extension has been going on during the past two or three centuries at the rate of nearly  $\frac{1}{2}$  sq. mile per year. Within this lower delta are vast areas of low land, part of it a few feet below sea level, that have been reclaimed from shallow lagoons and marshes by dikes and pumping, mostly within the past fifty years.

#### PROSPECTS FOR USEFUL INFORMATION—HISTORIC BACKGROUNDS

From a study of the literature it seemed highly probable that, by a brief personal tour of observation along this river, facts could be learned that would at least be of interest in the discussion, and, perhaps, in some small degree aid in the solution of the flood problem of the Mississippi and its tributaries.

The science of hydraulics had its birth in Northern Italy and was in part developed 400 to 200 years ago by some of the greatest scientists of any age: Leonardo da Vinci, Galileo, Torricelli, Castelli, Viviani, Guglielmini, Grandi, Manfredi, Frisi, and others in their efforts to restrain these torrents, and safeguard the inhabitants along the valley and the delta of the Po.\*

No region in the world was so rich in hydraulic literature up to 100 years ago, as this valley of the River Po. Some of the most ancient and famous universities and engineering schools of Europe, including those of Milan, Turin, Padua, Pavia, and Bologna, are located in and near this valley. Bologna claims the oldest university in Europe and Padua has one nearly as old. Pavia has been a center of study for more than 1 000 years. Columbus studied at its university, and, here, Volta made his first experiments. Foremost among "the old masters" of hydraulics were Michelotti, a professor at Turin; Frisi, a professor at Milan; and Poleni, at Padua. Guglielmini, who wrote the foremost treatise of his time, in 1697, on "The Nature of Rivers", was head of the Department of Mathematics in the Royal Academy of Science at Bologna and from 1700 to 1710 a professor at the University of

\* The Pontine marshes, which present problems of drainage that have engaged the attention of several of the most eminent engineers of Europe, are not connected with the River Po. They are located near the west coast, about 50 miles south from Rome.

Padua.\* The 11 remarkable volumes comprising, in their 5 500 pages, no less than 63 separate treatises by Italian hydraulicians of the preceding centuries, on the motion of water and the control of rivers, collected and republished more than 100 years ago under the title of the "Nuova Raccolta", was printed at Parma and Bologna within this region and related largely to the River Po and its tributaries.† Frisi's famous treatise on rivers and torrents, the world's outstanding book on these matters a century and a half ago, twice translated for the benefit of English engineers in India, deals mainly with the problems of this valley of the Po. History shows that from 1 000 to 200 years ago the Po was restless, meandering, and occasionally changed its bed. Frisi states that many centuries ago the river divided into several branches between Piacenza and Parma and converted a considerable part of Lombardy into a swamp which has since been circumscribed by dikes, while the river has been confined to a single channel. Ancient treatises presenting conditions of 900 to 1 000 years ago describe vast swamps that have since been transformed into agricultural land along the lower 170 miles of its course.

About 800 years ago the down-stream portion of the Po turned to the north, forming the Venetian branch, which gradually increased and for a time absorbed the water that formerly flowed into the southerly branches. About 325 years ago, after the Reno, which flows northward past Bologna (Fig. 2), had become so obstructed by sediment that it ceased to flow into the Grand Po, its waters spread over the shallow "valleys", or lagoons of San Martino, which thereby became filled and fertilized by sediment. Farther down stream these waters from the Reno, unconfined by dikes and without a permanent river bed, for a time ruined some of the most fertile land in Italy, formed vast swamps, and reached the sea slowly by the Po di Primaro. The Grand Po had formerly received both the rivers, Panaro and Reno, on its way to Ferrara, and, some miles below that city, it formerly divided into two branches, the Primaro and the Volano.

Frisi states further that the Reno and the Po are the two rivers that more than all others had engaged the attention of the Italian scientists, although the Arno and the Tiber also gave them much concern. The foremost mathematicians and scientists of Italy were called upon to find a remedy for the swamps and shifting waters of the Reno and the torrents lying easterly from it. They proposed to force the Reno to re-enter the Grand Po. Political obstacles, divided councils, accidents, and outbreaks long delayed the work, but finally the Reno was separated from the Grand Po and diverted into the old channel of the Primaro (Fig. 2).

Parts of the present channel of the Reno-Primaro, as outlined on modern maps, give evidence of artificial origin by their straight course. This channel was constructed within the southern edge of the great valley, and now gathers in various torrents—the Reno, Savena, Idice, Sillano, etc., flowing northward from the slopes of the Apennines, after they have dropped their loads of gravel in their separate delta cones subsequent to entering upon the more

\* Bologna is in the same valley on the River Reno that discharges into the Po di Primaro, which was the main channel of the River Po in the remote past.

† A full set of these remarkable books is in the Engineering Societies Library, New York, N. Y., the gift of Professor Fantoli, head of the Engineering College of Milan.

gentle slope of the valley floor. This information and much more that can be found in Frisi's treatise and in the eleven volumes of the "Raccolta", make it plain that this remarkable river and valley have received through the past four centuries the attention of the foremost engineers and physicists of the times.

Two hundred years ago the Reno, near Bologna, formerly a tributary to the Po, seems to have given more trouble than the main river, and, in 1700, Frisi was called in for further study. He has much to say about the raising of river beds, but it pertains to rivers of much steeper slope than the main Po, and mostly applies to the Arno, which flows past Florence and Pisa. His views still make interesting reading, and indicate plainly that the instances of elevation of river bed were not on the main River Po, nor caused by confining its waters between dikes and preventing the spread of sediment over the land. The troublesome elevations of river bed occurred on the tributaries near where they left the steep slopes of the narrow valleys and entered upon the much more gentle slope across the broad valley floor, where the lessened velocity caused them to drop their burden of gravel.

Frìsi argued that any new channel for carrying the waters of the Reno and the five torrents easterly therefrom to the sea, should have its pathway laid out well over into the valley floor of the Po, so as to receive the many torrents and small rivers that drain northward at a point beyond where they deposit their load of gravel brought from the hills, or beyond their gravel delta cones; and he appears to have felt certain that after a river had dropped its burden of transported gravel and carried only fine sand, it would not build up its bed. The main River Po drops its burden of gravel and coarse sand up stream from Cremona, or 160 miles above its mouth.

Frìsi emphasizes gravel as a cause of restlessness in rivers, and states that the main Po drops its own load of gravel where it enters upon its relatively gentle slope at the head of the main valley, and that it receives little or no gravel from its many tributaries. Frisi's views as to the influence of gravel may have important application to the cross-over bars of the Mississippi, which are among its most troublesome features.

His books also relate that spillways for ameliorating flood conditions were actively considered along these Italian rivers more than 150 years ago, and, in general, were found to be inexpedient or unsuccessful; but these were relatively small affairs. After reading Frisi, one has a strong desire to extend his historical studies and make inspections all along the Reno from Bologna to the sea, but the writer had not time for this.

#### A TOUR OF INSPECTION

After preliminary talks with two or three of Italy's foremost hydraulic engineers, Professor Gaudenzio Fantoli, at Milan; Luigi Luiggi, Hon. M. Am. Soc. C. E., and Mr. Lorenzo Allievi, at Rome, who provided kindly introductions to the chief engineers of river control in the Department of Public Works, the writer spent four or five busy days inspecting the delta, the dikes, and the channel of the Po and the Adige Rivers. He traveled by automobile back and forth about 200 miles, largely on well-kept roads on tops

of dikes, crossing and re-crossing the rivers repeatedly by bridge and ferry, and thus seeing much of them, their dikes, and the valley floor. This inspection included much of the way from Piacenza, past Cremona, Parma, Mantua, Padua, Ferrara, and Rovigo to the Adriatic, thence back to Ferrara, and across the valley floor to Bologna. The centuries of intensive cultivation and sub-division have given far more numerous cross-roads than there are along the Missouri, and nearly every road traveled was on top of an embankment that would form a secondary dike in case of need.

Many of the main dikes were said to be hundreds of years old, but had been repaired, raised, and thickened from time to time. Their permanence of location seems to indicate a less unruly river than the Missouri or Mississippi. Nevertheless, one look at the map of roads embanked on top of secondary dikes and at their curves which evidently follow old river bends, shows that this river has in past years sometimes meandered far outside its present pathway. (See Figs. 4 and 5.)

On most of the trip the writer was accompanied by one or another of the engineers in charge of the new work. The journey was extended by boat to the end of the principal delta mouth, where works are in progress for creating and maintaining a broad channel about 1 000 ft. wide, through the bar, suitable for barges of 600 tons capacity.

The tour was full of interest, the roads were excellent, and the farming was intensive, the fertile ground being burdened with crops, rice, maize, hemp, and forage. Economy in use of the land was shown by the long rows of trees along the cross-roads, planted to give forage for silk worms, and by occasional recent plantings on the foreshore, outside the dikes, of long parallel lines of poplars, about 12 ft. apart, for future wood pulp. There are now many broad strips of land of small utility lying between the main dikes and the river, which apparently it is the intention to reclaim for more intensive cultivation after the flood channel has been further stabilized and narrowed by works now in progress.

Everywhere the greatest courtesy was extended, many maps and reports showing features of special interest were furnished, and one was made to feel that the Italian engineer has a most kindly feeling toward his American co-worker. Space permits only a few of the observed features of special interest to be given.

#### WHAT WAS SEEN AND HEARD ON THE TOUR

All things considered, the writer knows of no more ambitious, courageous, and carefully planned project of river regulation now going on anywhere in the world than that in progress upon the Po, nor of any which rests on a more painstaking preliminary scientific study of the river itself.

For a number of years, a new hydrographic survey has been going on in the Valley of the Po, largely under the direction of Professor Mario Gandotti, following the recommendations of a Royal Commission of Engineers chosen from the most eminent in Italy, on which were Luigi Luiggi, Gaudenzio

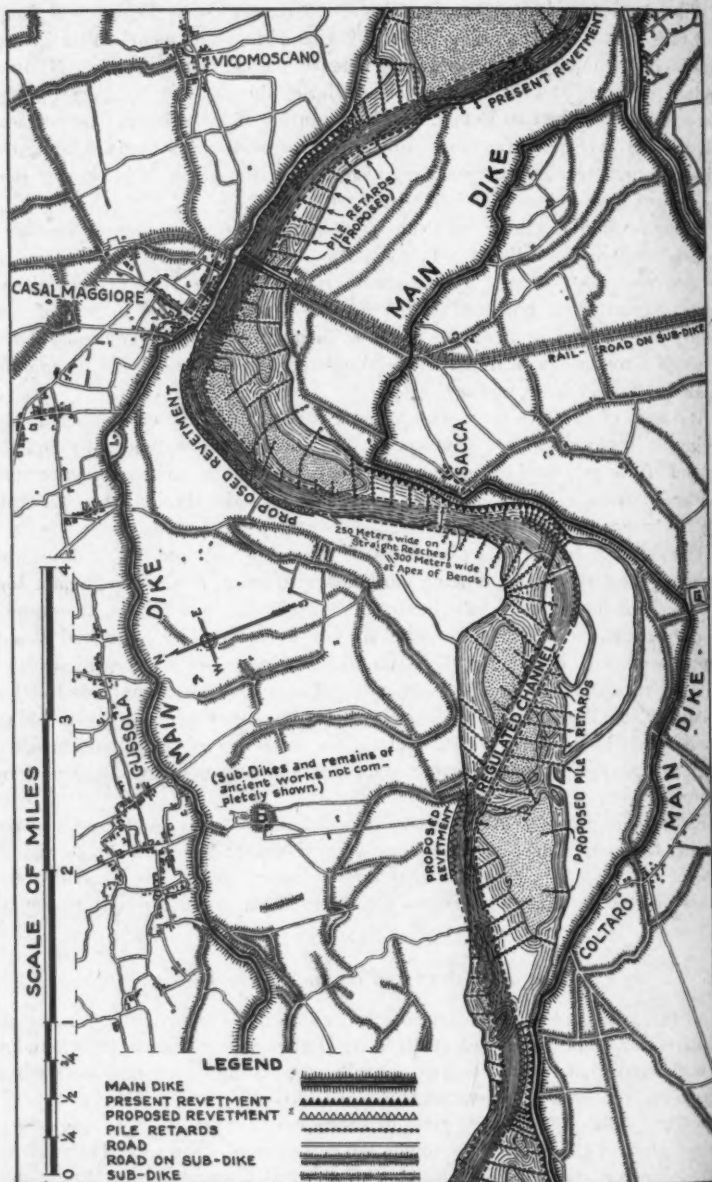

FIG. 4.—PRESENT AND PROPOSED CHANNEL AND REGULATING WORKS NEAR CASALMAGGIORE IN 1919.

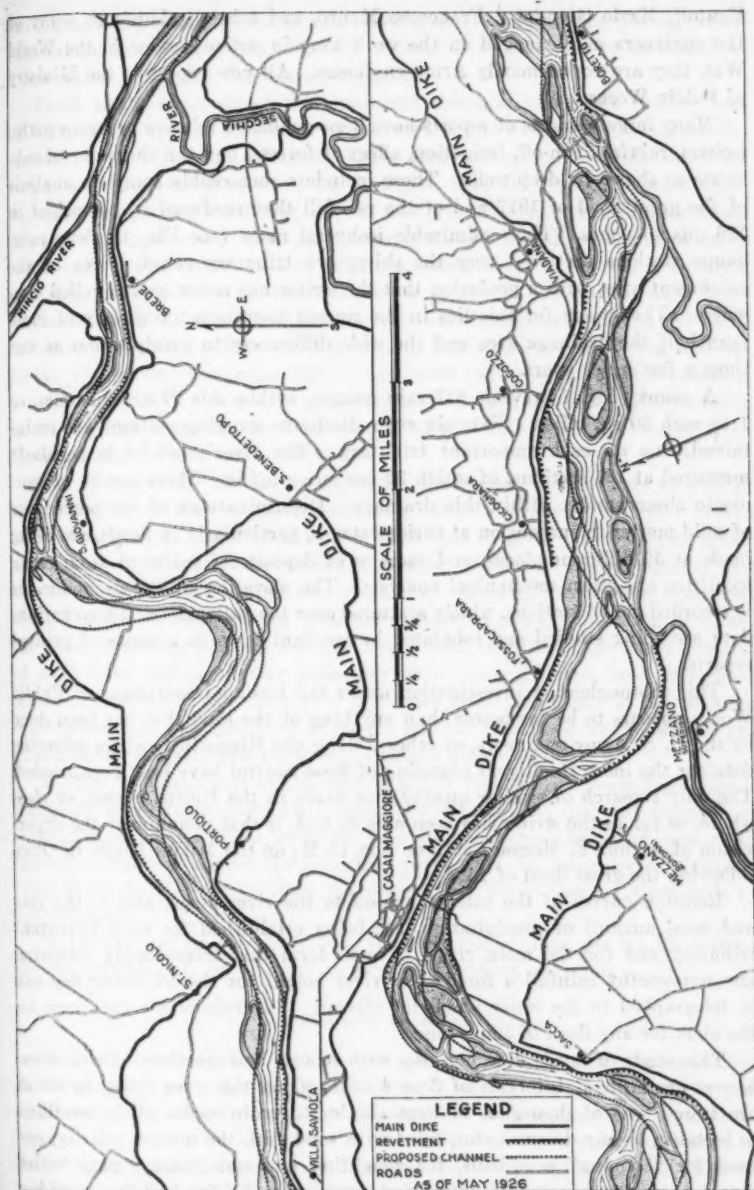

FIG. 5.—SECTIONS OF RIVER PO, SHOWING TYPICAL REGULATING WORKS AND PROPOSED CHANNEL.

Fantoli, Mario Giandotti, Francesco Mauro, and others. Although many of the engineers now engaged on the work were in active service in the World War, they are not primarily Army engineers. All now report to the Ministry of Public Works.

Many large volumes of reports have been published relative to storm paths, isobars, rainfall, run-off, irrigation, effect of forests, and the character of substrata as shown by deep wells. These include a remarkably complete analysis of the great flood of 1917 and of the rainfall that produced it, comprised in 186 quarto pages. Their admirable isohyetal maps (see Fig. 1) show rain-gauge stations scattered over the thirty-two tributary sub-divisions of the catchment area, with a profusion that the writer has never seen equalled elsewhere. The reason for this lies in the rugged mountain topography of more than half the drainage area and the wide differences in precipitation at stations a few miles apart.

A count (Fig. 1) reveals 917 rain gauges, within this 27 500 sq. miles, or 1 to each 30 sq. miles. Sixty-six river discharge gauging stations are maintained, one on each important tributary. The river's height is regularly measured at 137 stations, of which 32 are autographic. There are 33 meteorologic observatories within this drainage. Determinations of the percentage of solid matter in suspension at various stages, particularly in floods, are being made at 52 different places, and samples of deposits of sediment from many localities are given mechanical analysis. The elevation of the ground-water is recorded at 123 stations, widely scattered over the valley floor. These various data are being studied and tabulated in excellent form in a series of printed reports.

This thoroughgoing investigation under the Italian Department of Public Works appears to be far better than anything of the kind that has been done by the U. S. Army engineers, or others, along the Mississippi, where scientific data for the more intelligent planning of flood control have long been needed. The only research of similar quality ever made in the United States, or elsewhere, as far as the writer has been able to find, is that done under the supervision of Arthur E. Morgan, M. Am. Soc. C. E., on the Miami River, in Ohio, following the great flood of 1913.

Relation curves of the rate of run-off to the river stage, also to the rate and total amount of precipitation, are being established for each important tributary and for the main river, in such form that immediately following any noteworthy rainfall a forecast of river height for the following day can be telegraphed to the cities along the stream. Supervisors are thus kept on the alert for any flood of importance.

This study of floods does not stop with reports and treatises. Brick storehouses are built at intervals of 3 or 4 miles along the river dikes, in which are stored tens of thousands of bags similar to grain sacks, all in readiness to be taken to any danger-point, filled with sand with the utmost celerity, and used for "hooping" sand-boils, for weighting and stabilizing a bank which threatens to slip because of saturation or pressure, or for building sand-bag coffer-dams on top of the dikes. The peasant farmers of the broad countryside

are organized in readiness for extreme floods, each man knowing his appointed place along the dikes, so that literally thousands of men can be mobilized at a few hours' notice for defence at any point.

Proof of the efficiency of this organized foresight was given in the flood of 1926, which was the greatest ever recorded in the history of the Lower Po. In May, 1926, following extremely heavy and widespread rainfall, the river rose to a height averaging about 1.3 ft. higher than the top of the main dikes for many miles along the Lower Po, but was prevented from overflowing them. About 30 000 men are said to have been mobilized and, in addition to other work, built a continuous line of sand-bag coffer-dams, from 2 to 3 ft. high, and more than 30 miles in total length, so promptly and quickly that there was no break in the dikes down stream from Casalmaggiore, or along the lower 130 miles of the river. This was a wonderful performance, considering that the period of warning was remarkably short, and that the tributaries entering the flat valley floor are mostly short, steep, mountain torrents. The distance in an air line from the farthest corner of the water-shed up stream from Casalmaggiore is only about 190 miles.

The middle of the Po Valley, above Casalmaggiore, did not fare so well in the flood of May, 1926, or in that of June, 1917. Here and there were breaks and overtopping of dikes such that a large area of farm land was put under water, and city streets were flooded 2 to 5 ft. in depth. Photographs of the flooded districts bear striking resemblance to scenes the writer has witnessed along the Mississippi. There were the same sand-bag dams on top of dikes, the same weighting of insecure dike slopes with sand-bags, the same hooping of sand-boils, and a similar gathering of women, children, and household goods on the tops of the dikes that protruded from the flood. It is a strange coincidence that the 1926 flood on the Po and the 1927 flood on the Mississippi should have each attained the greatest height ever recorded.

Within the upper part of the delta plain of the Po, up stream from Casalmaggiore, more fortunately than along the Mississippi, the vast network of interior dikes, one of which forms the base of almost every road and cross-road, appears to have restrained the flood that penetrated the main dikes. Judging from their shape, some of these old dikes mark the outline of river beds of centuries ago.

Works are now in progress (1928) for many miles along the Po, for raising the main dikes 1 m., or to 3.3 ft., above their present elevation.

#### DISTRIBUTION OF RAINFALL

The two maps, Figs. 1 and 2, are selected from among many contained in recent reports, as showing the remarkably uneven distribution of the precipitation caused by the contrasts in elevation and exposure to vapor-laden winds. The first (Fig. 1) shows the distribution of the average total precipitation for the entire year; and Fig. 2 shows that for the 2½ days, May 28 to 31, which caused the great flood of 1917, one of the most severe recorded within the past century.

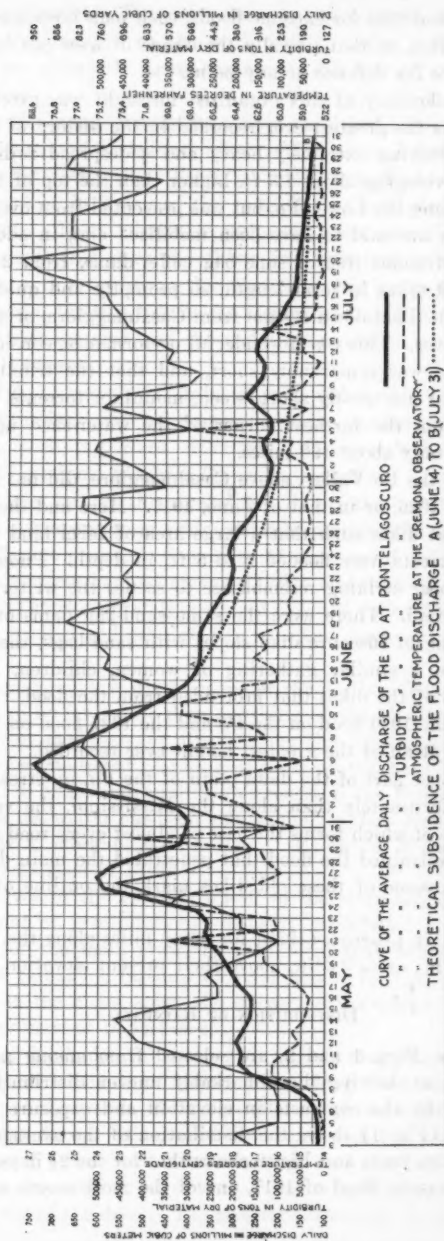

FIG. 6.—CHARACTERISTICS OF THE RIVER PO DURING FLOOD OF MAY-JUNE, 1917.

In Fig. 6 is shown the effect of the rapid succession of three heavy rain-falls which saturated the ground and led to the flood peak of June 1 to 5. It furnishes a measure of the flood in terms of cubic feet per second, while Fig. 7 presents it in terms of elevation of the river surface above the ordinary or low-water height at several important cities. Fig. 3 shows the daily rate of discharge for the hydraulic year, 1923-24, as well as the total number of days in the year upon which the river was above or below a given height or volume.

A glance at Figs. 1 and 2 shows the wonderful profusion of rain-gauges, stations for ground-water observations, river-gauging stations, and the wide variation of precipitation. The yearly range is from more than 120 in. in depth on mountain slopes to less than 20 in. in parts of the broad low valley, a ratio of 6 to 1.

From an inspection of Figs. 1, 2, 3, 6, and 7 it is plain that uncommonly complex problems of hydrology are presented on the River Po. The reports mentioned previously contain many other diagrams of scientific and practical interest. A map showing in detail the successive positions of this river within the historic period of 2 000 years would be of much interest, notwithstanding that for a century or more this stream has been held to the location in which it is now found. The writer knows of no such map, but the story of the control of this river will not be complete without one.

#### THE DIKE SYSTEM

A different arrangement of the dikes is presented along the lower river, below the ancient City of Ferrara, from that along the Upper Po. Along the lower river reliance appeared to be placed wholly on one main dike on each side of the river, whereas along the upper river there was a network of dikes. Along the Adige River near Rovigo there was a single line of dikes on each side, which appeared to be about 25 ft. high. The proximity of many ancient appearing buildings to these massive dikes indicated they had long held this river to its prescribed course.

At nearly all points seen by the writer, the main dikes of the Po had a top width of at least 16 ft., in other places of 23 ft., surmounted by a well graveled highway, excellently maintained. This appears to be better practice than that which prevails along many of the Mississippi levees, where the roads are kept off the top and placed along the inner terrace or berm, for the reason that water collecting in wheel ruts weakens the levee. Plainly, the remedy is to maintain a good hard-surfaced road width without ruts and with a high crown. Travel along the top of a dike scares away muskrats from burrowing into it.

The slopes on the river side were 1 vertical on  $1\frac{1}{2}$  horizontal. At the concave bends this river slope was roughly paved above low water, and was revetted below low water with a loose pile of stone rip-rap a few feet thick; so that in case of undercutting, stones could slide down and protect the base. On the land side, the slopes were 1 vertical on 2 horizontal, with one or more berms 5 to 10 ft. wide, at intervals of about 15 ft. in elevation. The height of the Po dikes above the fields was apparently about 25 ft., at a distance of 125 miles

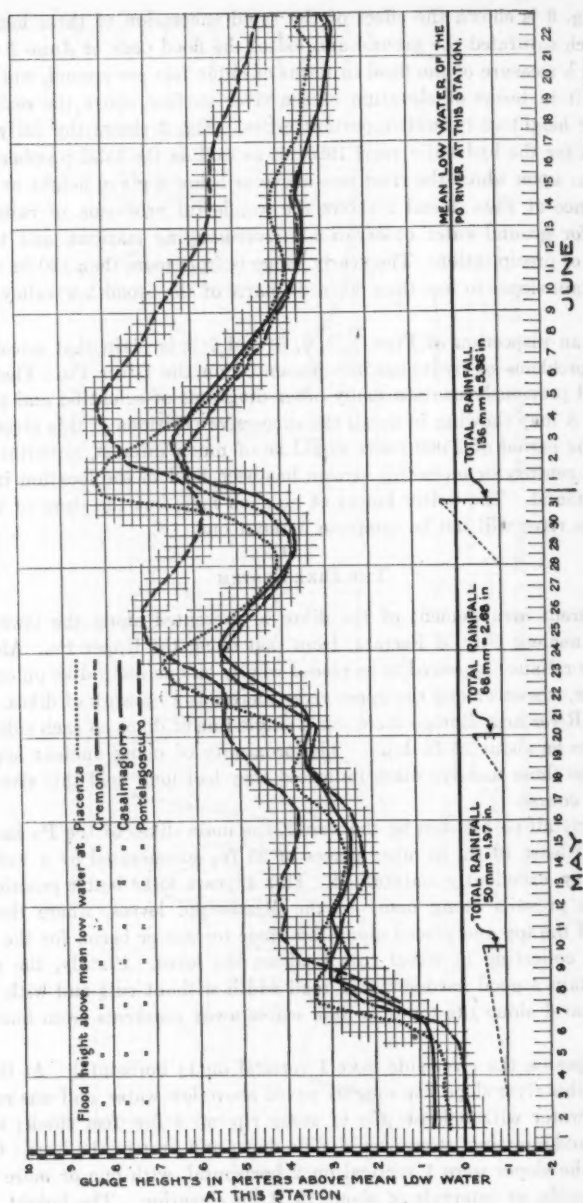

FIG. 7.—FLOOD HEIGHTS AT PIACENZA-CREMONA-CASALMAGGIORE-PONTELAGOSCURO DURING THE PO RIVER FLOOD OF MAY-JUNE, 1917.

from the sea. At some places the height is said to be greater and dikes 45 ft. high are said to exist on some of the tributaries.

**Dike at Concave Bends.**—Fig. 8 shows a standard cross-section of a sturdy structure, 23 ft. wide on top, well adapted for a highway, and considering the quality of fine sand of which it is built, sufficient in thickness to escape saturation and sliding during the short-lived floods of the Po. The sand of which these dikes are built appears in general to be composed of grains  $\frac{1}{16}$  to  $\frac{1}{80}$  in. in diameter, through which saturation would proceed slowly; but that they are sometimes rendered dangerous by saturation was indicated by photographs taken during the great flood of 1926 of inshore banks completely covered with a layer of sand bags to stabilize them. This condition, however, was the result of three successive floods within 28 days, illustrated on Figs. 6 and 7.

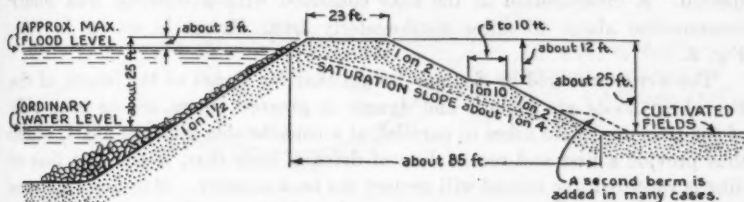

FIG. 8.—TYPICAL DIKE AT CONCAVE BENDS ALONG THE PO RIVER.

The material for dike building so far as noted, was extremely fine sand like that in the river bed and seemed to present no large proportion of slippery colloidal material. The conditions for dike building, as to material and sub-strata, appeared more favorable than along the Mississippi, with fewer soft swamps or old bayous to be crossed by the dike. Whatever of these soft spots there may have been in the days of earliest dike building, had been obliterated by centuries of intensive farming. Also, the shorter duration of the floods on the Po than on the Mississippi presents smaller chance for percolating water to penetrate through the dike and thereby softening and weakening it.

The only place where sub-surface conditions could be observed was at excavations for a new navigation lock on the river bank at Ferrara, for navigation from the main River Po southward through a canal to the Po di Primaro and the River Reno. Here, the ground for a depth of about 10 ft. below the natural surface was of clean, fine sand that apparently would pass a sieve of 50 meshes to the inch and was tolerably free from organic matter. Beneath this, the excavation showed a darker colored stratum of rather stiff, clay-like material of a consistency so weak that the steel moulds for concrete sheet-piling, apparently 30 or 40 ft. in length, sank rapidly beneath the dead weight of a heavy pile-driver ram, without a blow, to a depth of 20 ft. and were sent to full depth with relatively few 5-ft. drops of the ram.

From all that could be learned in this brief visit the dikes along the Po and Adige Rivers were in far less danger from undercutting and sliding inward during a flood than those along the Mississippi. This might be expected, because of their smaller depth which, in greatest flood, presents a bank-face on the concave shore of only one-half or one-third the height found in many places along the Mississippi. Moreover, the writer judged that along

the Po there is an absence of submerged snags or water-logged trees from caving banks to give the current a vicious twist against the bank. Local conditions apparently do not call for a broad protecting mattress on the river bed at the foot of the bank slope as on the Mississippi. Safe resistance to the underscour of the flood currents of the Po, even at the sharpest concave bank, apparently can be secured by a relatively thin breastwork of fascines, pinned down and stiffened by a few rather slender piles, and weighted with stone rip-rap.

A completed training wall of this kind near Casalmaggiore, which successfully withstood the great flood of 1926, was inspected. Another training wall, under construction, about 10 miles up stream from Parma, also was inspected. A cross-section of the dike combined with a training wall under construction about 10 miles northwesterly from Parma is shown in (E), Fig. 9.

The writer was told by Senator Luiggi that for a part of the length of the Po, where floods are highest and danger is greatest, there are on each side of the river two main dikes in parallel, at a considerable distance apart, which thus provide a first and second line of defense, such that, if the first line of dike is ruptured, the second will protect the back country. Moreover, the area between the two dikes presents a noteworthy addition to the reservoir capacity of the river. The writer did not happen to see any clear cut examples of this double dike with reservoir space between, but found in the region between Cremona and Casalmaggiore an equivalent protection afforded in the multiplicity of secondary dikes beneath the highways and cross-roads, some of which on curved lines parallel to the river, apparently marked the shore line of centuries ago. (See Fig. 4.) In many places a third lesser dike has been built close to the water's edge by the farmer to permit the utilization of an additional strip of ground, with the expectation that this will be drowned out once every 5 or 10 years. There is, moreover, a system of major and minor dikes along much of the river, as illustrated by Fig. 10.

Everywhere, at short intervals along all the dikes, were broad ramps carrying the road down to the level of the cultivated fields. Some of these main outer dikes present a slightly zig-zag alignment, for which there was said to be some military reason, there being a main highway along the top.

This network of main roads and cross-roads, each on top of an embankment about as high as the main dikes, which were found all along the river from Cremona to Parma, presented a great safeguard against widespread inundation, which was mostly absent down stream from Ferrara to Rovigo, or within the lower delta. Districts along the down-stream portion of the river obviously need less substantial safeguards than midway of the stream, because of their multiplicity of old channels by which the water can escape quickly to the sea.

#### THE RIVER CHANNEL

The average impression left in the writer's memory, after inspecting the River Po at many points from Piacenza to the sea, at a stage about 3 ft. above

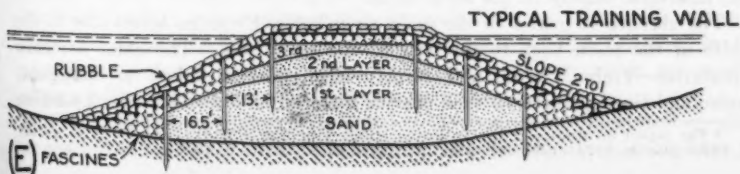

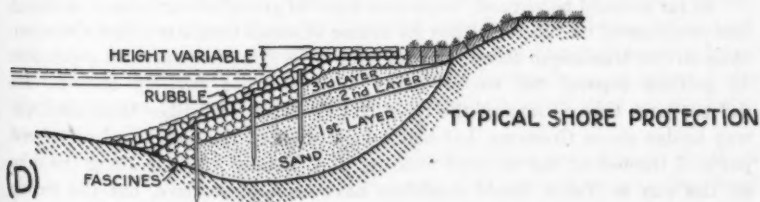

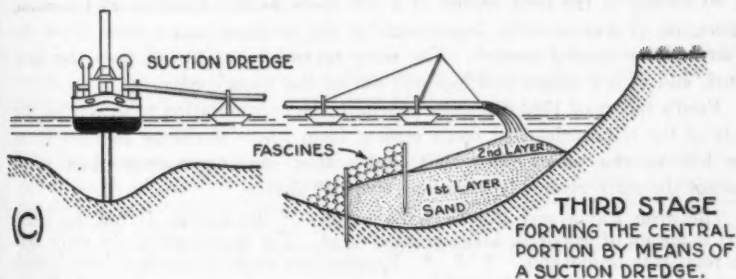

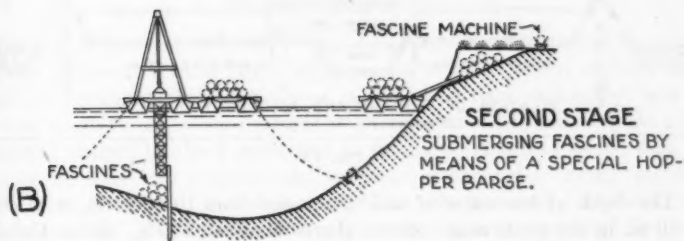

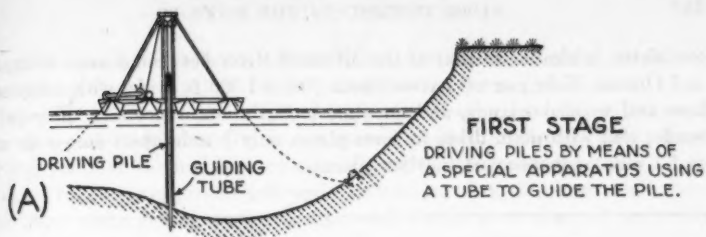

FIG. 9.—BANK PROTECTION AND TRAINING WALL FOR RIVER PO.

low water, is similar to that of the Missouri River between Kansas City, Mo., and Omaha, Nebr.; or of a river about 700 to 1 000 ft. wide, with many sand-bars and wooded islands, and an almost continuous succession of loops and bends; and with main dikes in some places only  $\frac{1}{4}$  mile apart across the river and 1 mile or more apart in other places.

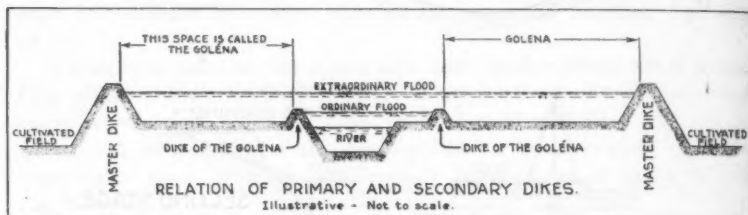

FIG. 10.

The depth at low water is said to average from 10 to 20 ft., with depths of 30 ft. in the pools near concave shores or sharp bends. Below Cremona, the bed shows no gravel and no sand coarser than would go through a sieve of 50 meshes to the inch, except at a few spots, as, for example, at Cremona, where, as at Kansas City, boats reclaim the medium coarse sand from the river bed for cement mortar. The river appeared less turbid than the Missouri, and at low stages had less soft silt at the water's edge.

Frisi's report of 1762 discusses at length the accumulation of gravel on the beds of the tributaries just down stream from where the slope changes from the hill to the valley floor, but states that nothing coarser than sand reaches the main river. It has been reported\* that:

"Between Pavia and Piacenza the nature of the bottom is for the most part made up of gravel or large grained sand. The materials of the river bed are relatively immovable. \* \* \* Excavations made by dredges have lasted in general for many months and in some cases even for years. \* \* \* From Piacenza to Cremona are found the last gravel and the first sands."

So far as could be learned, "cross-over bars" of gravel or coarse sand, are much less pronounced on the Po within its course of small declivity below Cremona, than on the Mississippi River, and its tributaries; but from certain statements in printed reports the writer infers they are not entirely absent. He did not have time to inspect the river and its banks and dikes from the highway bridge above Cremona, but had a brief view of the banks and uncovered parts of the bed at the railroad crossing at Piacenza. A tour along the dike all the way to Turin would doubtless have been instructive, but the writer was interested chiefly in the lower river.

The absence of gravel in the main river below Cremona seems due to the width of the plain back to the base of the steep hills. The chief northern tributaries—Ticino, Adda, and Mincio—flow through lakes, as Maggiore, Como, and Garda, where all such coarser material is deposited. The Apennine

\* The report on studies of the Po to the Ministry of Public Works, under decree of July 15, 1922, pub. in 1924 under the title, "Relazione ed Allegati," p. 48.

tributaries have no such lakes. Nevertheless, apparently, they fail to deliver gravel across the great width of the valley floor to the main river.

The proportion of fine silt and of slippery colloidal material in the main river when only 3 ft. above its lowest stage looked rather small, and perhaps this may simplify the problems of safe dikes with rather steep slopes.

These are the impressions left upon a rapid traveler. To answer all questions about bars, bends, caving banks, and stability of channel decisively would take far more time and facilities than were available.

#### REGARDING NAVIGATION

Increase in navigability is one of the chief purposes of the extensive works for river training, recently begun after several years of study, as previously described. Sand-bars in a few places in the lower river and gravel bars in the river above Cremona have presented obstacles on which considerable work by suction dredges has been performed in the past. It is now hoped that, by training the river into a single relatively narrow channel of nearly uniform width, the requirement for dredging will be largely decreased. The report to the Department of Public Works—previously quoted—expresses the hope (pages 48 to 50) that the delivery of sedimentary material into the river will at some future time be lessened

"\* \* \* by regulation works on the mountain sides, which, while adding to the safety of the habitations, and that of the roads and other public works, will also greatly help in the better maintenance of the depth for navigation by rendering the water less turbid."

Also, this report states:

"The dredging work may in time be notably reduced where, with the appropriate work of retaining, reforestation, and draining, provision is taken to regulate the mountain basins of the Apennine torrents, works which will undoubtedly result also in the efficient consolidation of the landslides which, especially in the Emilian Apennines, continually menace the roads and habitations."

Fifteen miles up stream from Casalmaggiore, the writer saw 600-ton barges laden with rip-rap from the hill quarries north of Padua, which he was told had navigated the river up stream from the canal lock about seven miles easterly from Adria without difficulty. No other boats of importance were noted except some fishermen's boats near the mouth. Evidently, navigation of the Po has not yet become active. Perhaps it awaits improvement at the lower mouth.

At the delta mouth there is a sudden shoaling from the ordinary depth of 10 to 20 ft. to from 2 to 5 ft. at low water for about  $\frac{1}{2}$  mile in length of course. From this bar, under present conditions, navigation for barges with drafts of 7 or 8 ft. may now be readily accomplished.

In the writer's opinion this shoaling at the exit doubtless is caused by the precipitant action of the sea water on the fine sediments which are carried along readily in fresh water by moderate currents.

Frisi and other writers, of from 100 to 200 years ago, mentioned shoaling at the mouths of other chief Italian rivers, and presented various theories as

to its cause. The favorite explanation had to do with drift, under the action of littoral sea currents, of sediment brought down by the river.

#### RIVER TRAINING IN PROGRESS ON THE PO

As a part of the recent widespread industrial activity in Northern Italy, river training has been begun for developing navigation on the Po and its tributaries. Connection by locks is to be made with the canals connecting with the Adige and the Reno to ports on the Gulf of Venice and on the Adriatic Sea, thereby serving the river cities all the way up to the great industrial districts of Milan. These works are designed to provide for steel barges of 600 to 800 tons capacity and of 8 ft. draft. The plans comprise, chiefly, training of the river into a curving channel of nearly uniform width of about 1 000 ft., with a narrowing at points of contraflexure instead of an expansion, such as is found in many places along the Mississippi, and which extra width, as explained by the late James B. Eads, M. Am. Soc. C. E., may be largely responsible for its bad cross-over bars.

The regulation of the Po is designed to give ultimately a width of 300 m. for the bends and only 250 m. for the transition sections between the bends.

This great public work was actively begun about 1926 after years of patient study and planning under Professor Giandotti and others. It is understood that the present plans are tentative and subject to modification as the work proceeds. In brief, the system is designed to make a limited amount of money go as far as possible with safety. It is proposed to protect and hold most of the concave shores in their present position by a revetment composed of fascines and rip-rap as outlined in (*D*), Fig. 9, without any mattress work. Where the river has to be narrowed at a wooded island or a "middle ground", training walls will be built of a type similar to that shown in (*E*), Fig. 9. The lesser depth permits these structures to be of much simpler character than has been found to be permanently reliable on the Mississippi.

It is hoped by those in charge that the total length of protection, by means of fascine and rip-rap like (*D*), Fig. 9, which will ultimately be required, will probably not exceed one-fourth the entire length of the river bank. This limited application of bank protection is obviously a matter of great economy, and it is expected that by holding the river thus narrowed to a uniform width, somewhat rigidly to its present curving course, in which it has long seemed content, and retaining its present length, elevation, and slope, that the Po will be satisfied to remain within the path now laid out for it, with protection only along the concave shore. The writer understands that the uniformity of width, with shore lines at the bends curved somewhat precisely to prescribed radii, all as shown on certain of the plans portions of which are copied on Fig. 5, is not expected to be produced forthwith, but is the ideal shore line toward which all the revetment and training walls will tend.

This retention of the present total curvature leaves the river 50% longer from the Adda confluence to the confluence with the Secchio, 82 miles down stream, than if the bends were cut out; in which case doubtless both banks would have to be reveted most of the way. Here and there, where the river shows a tendency to dig too deeply into a concave bank and thus threaten

the adjacent dike, one or more spurs of fascines and rip-rap have been built out at a slight angle to the current, to turn it back toward mid-stream. The success with which the dikes, remarkably close to the edge of the low water, are maintained by light rip-rap, and by protecting only the concave bank, indicates that the Po is far less restless within its banks than the Mississippi, and that its subsoil presents no such treacherous conditions as those which without warning caused the crevasses at Poydras and Wecama, La., and threats of crevasses at Tunica, Miss., Stanton, Miss., etc., during the Mississippi flood of 1922. There may have been difficulties of which the writer did not learn. The few days spent along this river were far too brief for studying all its possible vagaries.

It was of special interest that engineers of great experience and manifest ability, like Giandotti, Fantoli, Luigi, Mauro, and others of eminence, had evidently concluded that they could safely devote the limited funds available for improvements for navigation and flood control on the 82 miles of the River Po between the Adda and the 'Secchia, to confining it to a uniform width of about 825 to 1 000 ft., following nearly its present channel, without important change of total curvature, without making cut-offs across-bends for straightening, and with a total length of special bank protection and revetment amounting to only about 25% of the bank. The projected channel section is shown in Fig. 11.

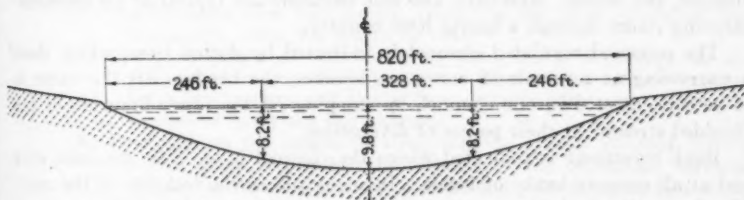

FIG. 11.—PROPOSED NORMAL SECTION OF REGULATED CHANNEL FOR THE PO.

The writer would have favored a more radical straightening and cutting out of bends, beginning near the mouth, thereby lowering the flood heights on the upper river and shortening the path for navigation, all, of course, subject to study and experiment in the field and in a hydraulic laboratory. Such a radical innovation would have cost more for the early stages and would have delayed the opening of systematic barge navigation. The method adopted is in the nature of "playing safe" and minimizing the immediate outlay.

In some reaches within this distance the space between the main dikes is now about a mile in width. Within this space the river has been free to meander, and alongside its main channel there have been deposited banks of sediment to such a height that the shallow depth over them in a great flood adds relatively little to the discharge capacity. The controlled narrowing to a uniform width of 825 to 1 000 ft. will add largely to land available either for cultivation of narrow forests of quick growing pulp wood, or for field crops enclosed by cheap low dikes that may be flooded once in 10 years. The present main dikes, farther back, will remain as a second line of defense.

In the early stages of improving conditions for navigation, much dredging has been done at shoal places; but the writer was given to understand that, in the future, it is hoped to avoid any large amount of dredging, except at the outlet bar where fresh water and salt water meet, the current, as guided by the new training walls, being expected to shape the future channel.

Professor Giandotti, and others, stated that they were basing the designs on intensive studies of the river itself, its actual depths, and its tendencies at various localities, rather than on experimenting toward any radical changes in curvature or in design of groynes or revetment forms by means of laboratory models. This is in marked contrast to the present practice of river engineers in Germany. This attempt to confine a great meandering river to a constant width with such a minimum of shore revetment at a minimum of cost is heroic and so far as the writer knows is unprecedented.

Notwithstanding they have been guided by centuries of observation on the behavior of this river and its neighbors, in developing their designs, the writer is confident that an adequate hydraulic laboratory could be of great aid and lead to great economies. They have a long way to go, and the proposed laboratory at Stra may yet be of service in their work.

In Figs. 4 and 5 are shown plans of short typical reaches, copied from maps on larger scale covering about 100 miles of the river's course that recently has been studied in much detail. The relative positions of the present main channel, the islands, sand-bars, and side channels are typical of all sediment-carrying rivers through a nearly level country.

The proposed regulated channel is indicated by dotted lines, which show a narrowing at reversals of curvature between the bends. All the water is to be concentrated in one channel, by stopping off the lesser branches of the "braided stream" at their points of divergence.

Bank revetment is indicated where the channel is close to the main dike and at all concave banks of bends. In many places the location of the main dike bears little relation to the present main channel. The width between them varies (Fig. 5) from hardly more than  $\frac{1}{4}$  mile near the confluence of the Mincio to  $2\frac{1}{2}$  miles at a location 6 miles up stream. Since the ground for miles around is an alluvial deposit of substantially the same texture, these relative locations of channel and dike are accidental and matters of ancient history.

Similarly, Fig. 4 shows details of the position of spur-dikes for confining the water to a single channel in a typical section. The current "retards" are simple lines of piling, against which floating rubbish lodges in time of flood, thus retarding the current and inducing deposits of sediment. As stated elsewhere, it is found necessary to strengthen the up-stream retards by cross-bracing, and, in some places, by spur-dikes armored with stone rip-rap. These pile retards are in purpose very much like the permeable dikes tried unsuccessfully on the Mississippi River many years ago.

#### BRIEF EXTRACTS FROM REPORT OF MARCH, 1924

In the report dated March 17, 1924, to the Minister of Public Works, Gabriello Carnazza, Deputato al Parlamento, by Engineer Leone Roman-

Jacur, Senatore del Regno, on the improvement of water communication from Milan to Venice, which makes, with its appendices, a volume of 236 pages, there is much of interest to engineers. Space permits only very brief extracts. On pages 45 to 51 are a series of questions and answers from which the following positive statements are condensed:

- (1) The pile retards exposed to strong currents have suffered injury, and for permanence require the protection of rip-rap. Those not exposed to strong currents have endured.
- (2) The effect in increasing depth of channel up to that time, when only a small part of that proposed had been installed, had not been specially noteworthy.
- (3) The safety of the main dikes had not been impaired by the obstruction to river flow caused by the pile retards.
- (4) From this experience it was deemed advisable to extend the works, but to limit the simpler form of pile retards to places not exposed to strong currents. Experience on the Tiber, Reno, Elba, and Vistula Rivers gave hope of success on the Po.
- (5) The recent studies showed an average discharge of sediment carried by the Po, of about 10 000 000 cu. m. per year. (Equivalent to about 8 300 acre-ft., or 13 ft. in depth on 1 sq. mile.)
- (6) This amount of material on its way to the sea impedes navigation by forming sand-bars where the river is broad at time of low water; and there are excellent reasons for expecting improvement to follow the proposed narrowing and the consequent increase of velocity, at low water.
- (7) Until means were lacking for confining the river, dredging was necessary. This was begun in 1910.
- (8) The permanence of cuts made by dredging is dependent on the material forming the river bed. There is a transition zone between Piacenza and Pavia, from gravel to fine sand, where the surface of the river bed changes.
- (9) Dredging, in the course of time, may be greatly reduced, particularly after reforesting the basins of the Apennine torrents. Works for regulating these torrents and preventing erosion along their course will greatly aid the works of regulation along the River Po.
- (10) From the studies of more than a century, the bed of the River Po presents no tendency to progressive rising. The sediments brought in by the torrents merely form temporary obstacles to navigation. Dredging will rapidly remove these obstacles, and, in course of time, after regulation and narrowing, the River Po may be expected to clear itself.

On pages 60 to 62, the conclusions of the Commission for various reaches of the river, are summarized as follows:

- (1) From Muncio to Carnavalla-Po, a small amount of dredging suffices to maintain channel depths for 600-ton barges save at a few places presenting exceptional conditions; here regulation works are needed. For the Adda-Muncio Tract, regulation works are needed to supplement dredging.
- (2) Trials on the most difficult section of the River Po, from Taro to Costello, instituted first of all from theoretical considerations, and without previous experimental data, seem to have been not altogether successful, but to have pointed the way toward improved structures promising success.

- (3) The conclusion seems to have been reached by the Commission, that navigation interests could be better served by regulating the Po for barges of 600 tons capacity, than was possible by means of a parallel system of canals, which would accommodate barges of only 250 tons, and that the river can be made a fine waterway from Venice to Milan similar to the principal rivers of France and Germany.

In pages 81 to 85 there is presented a summary of the study of the regulation of the Po at low water, by the Hydrographic Office of the Po. Many of the facts therein stated have been presented in the preceding pages. The following, however, seems worthy of special attention at the risk of repetition.

The tributaries of the Po comprise three groups of very different characteristics:

- (1) Torrential rivers from the Apennines, coming from the south in rapid impetuous floods, carrying much sediment.
- (2) Torrential rivers from the Western Alps, similar to Group (1), but with smaller precipitation and, therefore, bringing less sediment.
- (3) Those from the Alps, coming from the north, which flow through lakes and, with the exception of some small tributaries, deliver water free of sediment.

The floods in these groups come at different times, those from the Apennines first. The River Po commonly presents two low-water stages. The earlier Apennine floods leave obstructing sediments to be scoured out by the later floods of less turbid water from the north.

Cross-sections measured 10 years ago show no noteworthy change in area for low water, from those measured 50 years ago.

Measurements of average low-water elevations carried on throughout a century at Pontelagoscuro show undulations, but neither a progressive rising or lowering, thus proving no important change in elevation of river bed due to sediments unless it be that the climate and run-off have changed, which records disprove.

The turbidity measurements in the 7 years, 1914 to 1922, indicate an average annual transportation of 23 380 tons, or 17 450 cu. m. of silt, equivalent to 14 400 acre-ft. per year. (Note the estimate on page 187 of 8 300 acre-ft.)

Lombardini, more than a century ago, from the advance of the delta and the depth of deposit, estimated 27 000 000 cu. m. per year, of sedimentary material brought down by the Po, equivalent to 22 000 acre-ft. per year.

Marinelli from delta extension, from 1823 to 1893, estimated 29 000 000 cu. m., equivalent to 24 000 acre-ft. per year, as an average for the previous 70 years.

Also, some interesting details of the progress of the regulating works are given (pages 205 to 217 of the report just quoted) which are abstracted as follows:

The Minister of Public Works (Director General of Hydraulic Works) ordered the superior officers of the Civil Engineering Corps at Parma to present projects for increasing the navigation of the Po so as to permit the passage of barges of 600 tons at low water from the confluence of the River Adda to that of the Carnavalla-Po. The general plan is to unite all the low-water flow in a single channel with an area of cross-section sufficient to avoid too high a velocity of current for convenient navigation, while high enough to prevent obstruction by deposits of sediment.

The low-water discharge for planning the works was assumed to be 400 cu. m. (nearly 1500 cu. ft.) per sec., and the slope, 0.00018, or 0.93 ft. per mile in the 26 km. (16 miles) from the confluence of the Taro to that of the Erza, and 14 km. (9 miles) farther to that of the Crostolo.

One basic criterion of design was that the equilibrium of the river must not be disturbed at either high or low water.

In order that discharge at high water may not be hindered so as to raise the flood level, the new works were all to be designed with their tops not far above the low-water elevation.

In order to avoid changing the low-water regimen of the river, the regulated channel has been designed to have an alignment near that of equilibrium, as shown by the course of the low-water channel in recent years.

In prescribing the shape of the succession of curves and the straight reaches between them, attention was given to the rule deduced by French engineers, that the greater the regularity and continuity in varying the curvature of the concave bank, the greater the regularity of variation in depth. A parabolic curve was adopted as offering, at point of tangency, less discontinuity than a circular path. A surface width of 250 m. was adopted for the straight courses and increased to 300 m. at the apex of curves to provide for deposits of silt at the convex shore.

Two types of works were adopted: (1) At concave shores, protection works and revetment; and (2) for contracting and concentrating the low-water current, systems of piling retards and groynes and rip-rap are to be constructed in the convex and straight portions. These are designed to increase the deposits of sediment and ultimately to close all minor channels.

It was recognized that works directly opposed to strong currents, would have to be made of greater strength than works in more quiet waters, the piling at such places being strengthened by ties between them.

Construction was begun on the current retards during periods of low water. These consist of piles about 8 in. in diameter, 18 ft. long, sunk about 12 ft., with their tops slightly above mean low water.

Lattice work was constructed between the piles at first, but its use was abandoned later, because of the belief that at time of flood, the drift of weeds, etc., would lodge on the piles and serve the same purpose. Later, however, in order to hasten the deposit of silt, the use of lattice work was resumed.

Various directions of the lines of piling in relation to direction of current were tried. Trials showed that the piling was not injured where currents were sluggish, but that strong support for it was needed against swift currents. In general, methods and materials previously used in these localities were adopted as far as practicable.

Costly excavation by mechanical means was avoided, by inducing the current to do the work, until the desired position for the concave bank was attained.

The works completed in 1922 and 1923 and up to the date of this report (1928), comprise but a small portion of all that is contemplated. Progress has been delayed by lack of funds, but the observation of the behavior under stress of the great flood of 1926, of the works already constructed, gives valuable data for future work and so far as the writer could learn this experience is favorable to the methods originally proposed. The future progress of this work and its success are matters of great engineering interest.

#### NAVIGATION LOCKS

A very interesting two-part navigation lock of recent construction, about 450 ft. long and 33 ft. wide, with a minimum depth of 12 ft. on the sill, was

inspected on the north shore of the River Po about 8 miles easterly from the ancient City of Adria (which gave its name to the Adriatic), and 1 mile westerly from the Etruscan coast line of about 3 000 years ago that is marked by sand dunes. This lock permits ready passage of large barges from the Po, whatever its stage of flood or drought, to the great canal system leading westerly to Adria, northward to Padua and Venice, and eastward toward the sea by the abandoned Po channel of 350 years ago.

The dikes here are 23 ft. high, and this lock provides for 20-ft. lift into the Po at times of great floods. A lift of only about 5 ft. was in evidence at the time of the writer's inspection, with the Po 2.5 ft. above its lowest stage. This lift practically measures the fall in river surface of the Po in the 23 miles from this point to the Adriatic, and indicates an extreme flood slope within the Po, from this lock to the sea, of about 1 ft. per mile, and a low-water slope of roughly 0.10 ft. per mile through the lower delta.

Another lock now being built near Ferrara on the south shore, already mentioned, will give navigable connection to the River Reno.

There is a wonderful development of irrigation canals many hundreds of years old within the northern half of the valley floor. Many of these are fed from the Adda River, and interlock with navigation canals accommodating small craft, and which, in turn, interlock with main drainage canals, all in a way which the writer made no attempt to trace. Plainly, this valley was the ancient homeland of hydraulic engineering.

#### RIVER-STRUCTURE LABORATORIES

Inquiry and brief inspection of the technical schools at Milan and Padua indicate that the hydraulic laboratory idea has not yet taken an important part in Italy in the problems of river training. This, in the homeland of the "old masters" of hydraulic science, and coming immediately after a visit to ten of the leading hydraulic laboratories, and conferences with a dozen or more of the leading hydraulic engineers, of Germany and Switzerland, seemed unfortunate, in view of the great activity in development of water power and in the reclamation of salt marshes that is now (1928) going on in Italy, and the evident present deep appreciation of scientific education as a foundation for industrial development.

The writer inspected the magnificent new buildings constructed and equipped mainly from funds contributed by the industries and financial institutions of the Milan District for the Engineering College at Milan designed to accommodate 2 500 students. He also inspected the Engineering College at Padua which has accommodations for 1 000 students. At both institutions the hydraulic laboratories have small floor area and evidently are designed chiefly for use in undergraduate instruction. Those at Milan and Padua are excellent for that purpose, but they are not adapted for wide application of the doctrines of dimensional analysis, by means of small-scale models, to the great special problems of water power development, river training, and harbor design, like several of the hydraulic laboratories in Sweden, Germany, Austria, Switzerland, etc., where the designers of high dams, sluice-ways, and

harbor improvements are bringing their practical problems to the laboratory in increasing numbers year by year. That the hydraulic laboratory idea is now developing in Italy is proved by the elaborate report on hydraulic laboratories in other countries published about 1925 by Professor Ettore Scimini, of Padua. The writer was told that large laboratories had been delayed by lack of funds.

It is planned to build an excellent hydraulic laboratory at Stra, not far from Padua. Doubtless this laboratory will be at work helping to solve the problems of the Po long before the present extensive program is completed.

#### IMPROVEMENTS AT THE RIVER MOUTH

Some particularly interesting jetty work, recalling the Eads jetties at the mouth of the Mississippi, has just been begun for creating a navigation channel 12 ft. deep by 1 000 ft. wide, at the northern, principal entrance of the Po to the Adriatic. The depth and position of the mouths of the Po have changed greatly during the historic period (Fig. 12). At some early, perhaps prehistoric, time the main river doubtless discharged to the northeast toward Venice. About 2 000 years ago, the river easterly from Ferrara turned southward through a channel the remains of which is called the Po-Morto, or "Dead Po", and for many years was depositing its sediments in the lagoons at the northern end of the Gulf of Comacchio where maps show many remains of ancient channels diverging from the present river not far from Ferrara. Later, the river turned northward. About 300 years ago, the commercial interests of Venice feared that the mud brought down by the Po and being deposited in the Adriatic by this northern exit, would threaten the depth of navigation available to the ships of Venice. Therefore, they closed this north-flowing principal mouth. This closure turned the chief discharge of water and sediment to the east, not to the extreme south as of old, which perhaps they had expected. The channel improvement by jetty and dredging is at this present principal mouth. This is said to carry 40% of the entire discharge, the remainder being divided through several smaller mouths farther south (Fig. 12), that appear to show no tendency to enlarge.

Although the average depth of the Po for many miles up stream from the bar is said to be from 15 to 20 ft. at low water, for a considerable width of the channel, with greater depth in pools at concave bends, the channels at the junction of turbid fresh water with salt water suddenly shoal to a depth of only 2 to 4 ft. They also spread out over the bar to a much greater total width than up stream. This shoaling extends perhaps half a mile or a mile along the river's course, with very gentle slopes in both directions to and from the crest of the bar.

For defining the new channel across the bar, one long, straight training wall somewhat similar to that shown at (E), Fig. 9, but with a larger proportion of rubble stone, is being built at a slight angle to the approaching current, the impact from which should induce a deep channel near the wall. Several long, narrow cuts have been dredged across the bar within the future channel in order to determine its composition and hardness, and perhaps to invite erosion.

There is a strong hope that the construction of a second parallel training wall can be deferred, although the plans provide for it. Later, it may be found expedient to build obstructions across some of the other mouths of the Po so as to force a greater current through this principal mouth, but this is now believed improbable, because for some years past the present chief outlet has shown a tendency to increase in size.

#### ADVANCE OF THE PO DELTA

The steady advance seaward of the shore line of the Po Delta into the Adriatic during the past 2 000 years to the extent of more than 15 miles at the outward corner of its fan-shaped delta, which is about 50 miles broad from north to south, is both of historic and practical interest (see Fig. 12). To the writer this increased length of river appears to be an important factor in raising the bed and the low-water surface of the Po in its winding pathway through the lower valley, probably more important than any deposit of sediment caused by confining the floods between dikes. At a point which 1 000 years ago marked the river mouth at sea level, the river surface at times of high flood now stands 10 to 15 ft. higher than before and this must affect the height of the river bed and the height of the water surface far up stream.

A rough measurement of the effect of this pushing out of the delta in raising the elevation of the water surface, and perhaps, also, that of the river bed, was found in the reading of the Po River gauge at the lock near Donada, described previously. This stood at the equivalent of 4.3 ft. on a gauge said to have its zero at sea level which, neglecting tides, indicated a fall or slope of 4.3 ft. in about 20 miles of river seaward, while the discharge was such as to raise the river here about 1.3 ft. This indicates a low-water slope of about 3.0 ft. in 20 miles, a large part of which may have been over the bar at the river's mouth.

The newly made delta surface between the mouths appeared in general to be 1 to 1.5 ft. above sea level, explainable by the deposit being largely made from water spreading out in time of high flood and being caught in the grass and bushes of the marsh. A low reclamation dike is being thrown around the newly formed land. For the past two or three centuries the accretion has averaged about 300 acres per year.

Successive advances of the shore line are shown on the accompanying map, Fig. 12, traced from a recent study given the writer at Venice by Luigi Miliani, Director of the Works for the Lower Po. The shore line of the Adriatic in the days of the Etruscans, about 3 000 years ago, is marked by a long north-south line of low sand dunes rising 10 to 20 ft. above the level of the plain. The writer visited these dunes but found no reason that explained why they marked the shore line of that particular stage of development, and are not found along the later stages of its advance, other than that these sand dunes may have been the product of winds blowing landward across a sea beach which maintained a nearly constant position during many centuries while the river was discharging southward through the Po di Primaro, filling with sediment an ancient indentation of the coast at the peak of the Gulf of Comacchio.

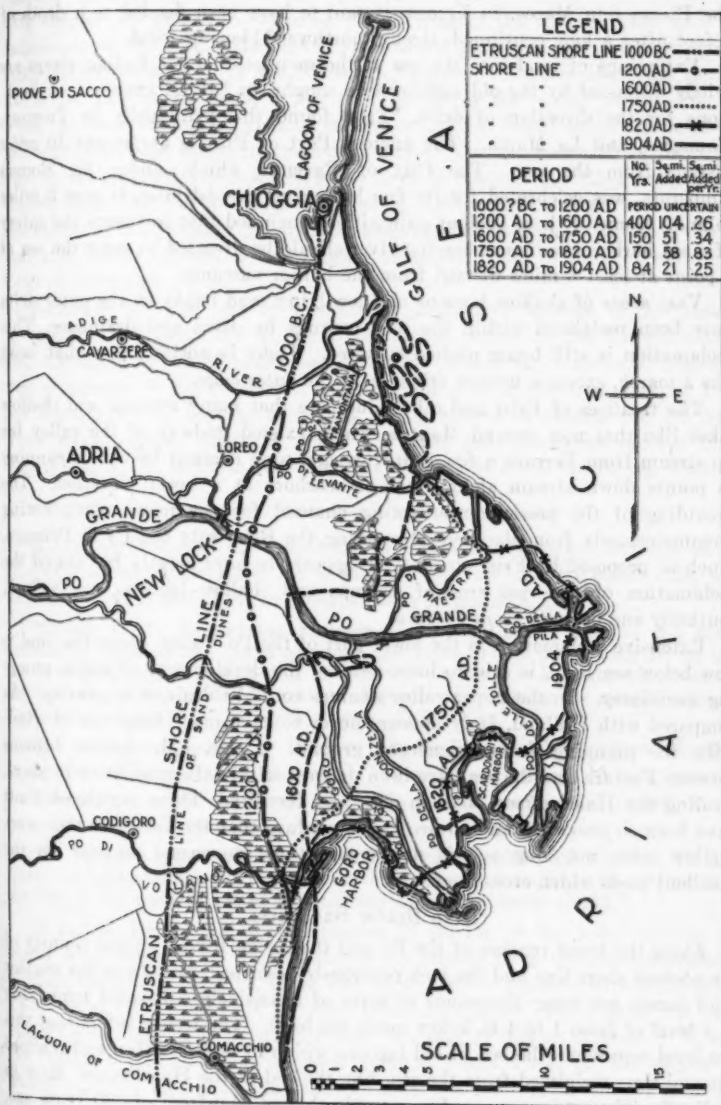

FIG. 12.—GROWTH OF THE PO DELTA.

The tides in the Adriatic, other than wind tides, are only about  $\frac{1}{2}$  ft. in range. A wind tide may lift the water as much as 5 ft. The pavement in the Piazza San Marco, in Venice, is said to have been flooded to a depth of a foot after a long-continued, strong, northward-blowing wind.

Extensions of land into the sea at the mouths of other Italian rivers are briefly discussed by the old authors who sought, in littoral currents, explanations for the direction of drift. Frisi found this principally in Tuscany, Romagna, and La Marca. The ancient Port of Pisa is at present 10 miles distant from the sea. The City of Ravenna which, under the Roman Emperors, was celebrated for its fine harbor on the Adriatic, is now 5 miles inland. Some of these ancient authorities concluded that to insure the safety of a sea harbor a sediment-bearing river should be diverted to enter the sea at a point at least 8 miles distant from the harbor entrance.

Vast areas of shallow lagoons and low-lying mud banks in the outer delta have been reclaimed within the past century by dikes and drainage. This reclamation is still being pushed outward. There is nothing now that looks like a marsh, except a narrow fringe near the outer edge.

The treatises of Frisi and others indicate that many swamps and shallow lakes like that now around Mantua, which existed midway of the valley far up stream from Ferrara a few centuries ago, were drained by canals running to points down stream along river or seashore at a lower elevation. The providing of the present intercepting channel for the many north-flowing streams easterly from the Reno, by taking the Reno into the Po di Primaro, much as proposed by Frisi about 1760, appears to have greatly facilitated the reclamation of the vast area of swamps and shallow lagoons, or "valles", southerly and easterly from Ferrara.

Extensive reclamation in the lower part of the Po Valley where the land is now below sea level, is said to have awaited the development of steam pumping machinery. In the upper valley swamps could be drained by gravity. As compared with Holland, Italy appears never to have made large use of wind-mills for pumping from submerged ground. Large, old, shallow lagoons between Ferrara and the sea have been drained within the past 50 or 75 years, rivaling the Haarlemmer Meer in area and fertility. These reclaimed lands have been so smoothed and covered with verdure that the fact that they were shallow lakes not long ago is not apparent to the casual traveler on the excellent roads which cross them.

#### LAND BELOW SEA LEVEL

Along the lower reaches of the Po and the Adige Rivers, in the vicinity of the ancient shore line and the lock previously described, west from the ancient sand dunes, are many thousands of acres of intensively cultivated land lying at a level of from 1 to 4 ft. below mean sea level. The writer infers that this low level represents the bed of old lagoons which have been diked and pumped out and thus reclaimed from the sea, like the bed of the Haarlemmer Meer in Holland. The ancient maps, for example that of Manfredi of 200 years ago, show many vast lagoons not noted on modern maps, but there are still many of these lagoons awaiting reclamation around the Gulf of Venice and the Gulf of Comacchio.

Local subsidence of the earth's surface as a cause for depression of these lagoons was suggested by authors of one or two centuries ago. Frisi, in his fifth chapter, discusses this in terms of the rising of the waters rather than of subsidence of the land. He says the continual rising of the waters was not unknown to the learned of the Sixteenth Century. Eustace Manfredi established the fact at Ravenna, a few miles south of the mouth of the Po, by levels on floors of several ancient edifices which he found below the level of the sea. Bernadin Zendrini confirmed this at Venice, where rings formerly used to fasten boats are now below the level of the sea, and the subterranean church of St. Mark is no longer serviceable. Lest this be thought to be due to settlement of the foundations, he cites observations on the opposite side of the Adriatic, where the sea is now higher than the floors of ancient buildings built on solid rock.

Naturally all this was of interest to the writer because of his recent investigation of earth tilt in the Great Lakes region in the United States and his discovery of 25 years ago, from old bench-marks and tide records, that subsidence at Boston, Mass., had been going on at the rate of about 1 ft. per century;\* also, because of finding in the course of studies for the New York water supply, about 23 years ago, that the tide-gauge records near New York, N. Y., indicate subsidence at the rate of about 0.6 ft. per century.

#### RIVER BED HIGHER THAN ADJACENT LAND

At the beginning of this paper the oft-repeated statement that the elevation of the bed of the River Po is higher than the land on either side, was mentioned. It is stated in the *Encyclopædia Britannica* that:

"Owing to its confinement between these high banks and to the great amount of sedimentary material which the river brings down with it, its bed has been gradually raised so that in its lower course it is in many places above the level of the surrounding country. A result of confining the stream between its containing banks is the rapid growth of the delta."

The writer was unable to learn of any valid complaint against the dike system of the River Po on this score. The statement appears to be untrue.

The report to the Ministry of Public Works, previously quoted, states most distinctly, on page 50:

"As seen from the said studies of the Hydrographic Office of the Po and from the hydrometric observations of the Po for a century, it is evident that the bed of the river presents no tendency to a progressive rising."

It is probable that on the tributaries of the Po, at the outer edge of the nearly level valley floor, immediately down stream from the steeper gradient of the river within the hills, there may be important deposits within the dikes which have raised the beds of these tributaries above the level of the land outside the dikes. The writer has seen examples of this on streams in Korea, but in this brief inspection no place could be found where the bed of the Po was at a higher level than the banks outside, nor could it be learned from the

\* See Appendix No. 20. Report by John R. Freeman, Past-President, Am. Soc. C. E., to the Committee on the Charles River Dam, Commonwealth of Massachusetts, 1903.

† See p. 653. Report of the Commission on Additional Water Supply for the City of New York, 1904, by William H. Burr, and the late Rudolph Hering, Members, Am. Soc. C. E., and John R. Freeman, Past-President, Am. Soc. C. E.

engineers of any such place along the main channel of the Po down stream from Cremona. Professor Scimemi, Chief of the Department of Hydraulic Engineering, in the Technical University at Padua, has written that he knows of no such instance from Mincio to the sea.

On the Adige River and other streams immediately north from the Lower Po, there are places where the bed is higher than the adjacent land. The Adige, unlike the Adda, Ticino, and Mincio, has no large lakes in its course. A cross-section, traced for the writer in the engineering office at Rovigo, is presented in Fig. 13. This section is about 22 miles up stream from Rovigo, or about 55 miles up stream from the mouth of the river. It shows the river bed 2.3 ft. higher than the land outside, and the water in the river 22.3 ft. above the land. Presumably, this was at ordinary stage, and flood stage was only 2 or 3 ft. below the top of the dike. In some other rivers, the bed is several meters higher than the land outside.

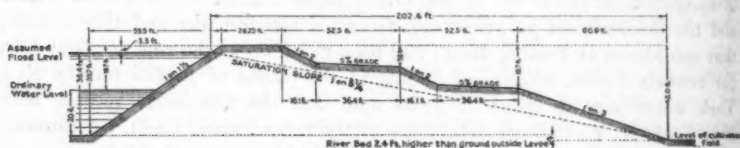

FIG. 13.—TYPICAL SECTION OF LEVEE ON RIGHT SIDE OF THE ADIGE RIVER.

On the Reno River where it leaves the steep slope within the hills south-westerly from Bologna, one would probably find similar examples. Time did not permit a tour along both the Reno and the Adige. The writer is confident that tracing these rivers from the sea, back into the slopes within the foothills, would disclose much of great interest to an engineer.

In closing this narrative it is suggested to the engineer tourist that, in addition to the art treasures of Florence, the marvels of cathedral architecture, or the mysteries of the Etruscan hill-cities, he can find in Italy plenty, both ancient and modern, that is of surpassing interest in the line of his own profession. The books of the "Old Masters of Hydraulics" also are fascinating. One who has scant knowledge of the language can translate much from analogy to the French and Latin of schoolboy days. The writer is trying to enlist the aid of some Italian engineers, including Lorenzo Allievi and Gaudenzio Fantoli, in preparing abstracts of some of these old treatises, which will trace the development of this branch of science and art in its early home, for the benefit of English-speaking engineers. The Italian backgrounds of hydraulic engineering present some very interesting scenery.

All that was seen and heard, of these works of river improvement, reclamation of marsh lands along the Po and farther south, and of the great activity in hydro-electric development of the highest order of excellence on Alpine streams, as well as the enterprise in technical education, the encouragement of general international scientific societies to come to Italy for their conventions in the year just past, indicate that Italy has taken a vigorous new departure toward prosperity, largely based upon modern science.

## DISCUSSION

C. McD. TOWNSEND,\* M. Am. Soc. C. E. (by letter).—The writer considers this paper the most valuable of the numerous productions on river hydraulics which have been evolved as a result of the flood of 1927 in the Mississippi Valley. While it contains numerous data which would be otherwise unavailable to most readers, its great value arises in that it recognizes that the science of river hydraulics existed in Italy prior to the discovery of America, and that Italian engineers have been engaged for centuries in investigating the laws governing the flow of water in streams.

While they may not have established laboratories satisfactory to the author, they have made practical experiments on the River Po for generations which are of much greater value. They have published and analyzed the results of their experiments, recording not only their successes but their failures. The description of the attempts to restore the river to the Grand Po after the break occurred near Ferrara, should be read carefully by those who would invite a similar catastrophe in the Mississippi River when constructing spillways.

The great value of the observations arises not only from the thoroughness with which they were made, but also from the long period of time which they embrace. German engineers have demonstrated that the construction of levees has not raised the bed of the Rhine below Lake Constance; those of France have arrived at a similar conclusion from an investigation of the flow of the Loire; and the Mississippi River Commission can find no trace of a river fill due to construction of levees on the Mississippi. The geologist, however, ignores these statements and continues to rely on M. Proney's report of the rising of the bed of the Po at Ferrara as recorded by Cuvier, notwithstanding the fact that it was denied and ridiculed by Italian engineers at the time it was made. It has also been claimed that the bed of the Yellow River has been raised due to levee construction. It is, therefore, a valuable addition to the science of river hydraulics when so great an authority as Mr. Freeman asserts, not only that the raising of the bed of the Po has been "found to be mostly untrue", but that the reports about the Yellow River "are mostly untrue, although not entirely so."

Another fallacy which has embarrassed river engineers is the assertion of Gustav Wex in a series of papers published from 1873 to 1879, that deforestation and drainage have caused a rise of the bed of the Danube. Schlichting and other German engineers analyzed the discharge of both the Rhine and Danube, and came to the conclusion that the little effect on the bed of these rivers which had occurred could be ascribed more logically to other causes. The masterly paper by G. Fantoli on "Il Po nelle Effermeridi di un Secolo" conclusively demonstrates that the only injurious results on the regimen of the Po caused by human agencies, have arisen from the diversion of water for irrigation; and that neither levee construction, deforestation, nor drainage has had an appreciable effect on its flow. Similar conclusions have also been derived from an analysis of the flow of the Upper Mississippi.

\* Col., U. S. A. (Retired), Washington, D. C.

Frisi and others decided that the troublesome elevations of river bed occur on the tributaries near where they leave the steep slopes of the narrow mountain ravines and enter upon the much more gentle slope across the main valley floor, and that gravel deposits are found in the upper reaches of the river, while in the lower sections the river bed is composed of finer material readily moved by moderate river currents. These deductions explain the cause of the errors committed by geologists, and indicate why they so readily accept, without investigation, any statement that the bed of a river is rising.

It is unquestionable that mountains and hills are eroded during rain storms and that the material thus moved is deposited in the valleys of streams or in the sea at their mouths. The geologist, however, fails to recognize that there exists, near the head-waters of every valley, a zone of deposition where the heavier portions of the eroded detritus are deposited, and that only the portions readily carried in suspension find their way to the sea. Succeeding floods again set in motion the material first deposited, but the grinding which ensues converts boulders into pebbles, pebbles into gravel, and gravel into sand, and in a relatively short distance gravel-bars are converted into sand-bars capable of being readily acted upon by river currents. This action occurs, not only on the tributaries of the Po, but on the Rhine above Lake Constance, and on the hill streams emptying into the Upper Mississippi. It is a rational explanation of the fill noted by the author on the Yellow River,\* as this fill occurs below a point where the river debouches from a mountain gorge.

As the writer has explained in various pamphlets and statements, most of which have been interred in the *Congressional Record* and the proceedings of Congressional committees, the engineer in charge of the improvement of the navigation of rivers is only interested in that section of a stream which has been brought into unstable equilibrium by this grinding process. In this part of a river, the cause of the rise of the bed is its extension into the sea, as discussed by Mr. Freeman.

The writer has inspected both the Po and the larger rivers of France and is somewhat familiar with European literature on river hydraulics prior to the World War. He has had no opportunity to read the report of March 17, 1924, mentioned by the author, but he has studied the *Atti del Comitato Tecnico Esecutivo, Commissione per la Navigazione Interna, decreto 14 Ottobre, 1903*, in which, while suggesting the improvement of the Po by the French system of river control, the Commission recognizes the success of the dredging operations on the Mississippi River in maintaining a channel, and proposes further experiments with dredges before definitely adopting the project.

It is to be inferred from the statements made by the author, that the Italian engineers have finally adopted the report of October 14, 1903, after making experiments extending over a period of twenty-four years.

One of the United States Army Engineers recommended a similar project for the improvement of the Upper Mississippi River in 1898.† The improvement of the Missouri River is based on the same principle.‡

\* "Flood Problems in China", by John R. Freeman, Past-President, Am. Soc. C. E. *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1422.

‡ H. R. Doc. No. 1287, 61st Cong., 3d Sess.

The system of river improvement adopted for the Po has resulted from experiments made by M. Fargue on the Loire River in France and by M. Gerardin on the Rhine. It is the system which has received the approval of the Ecole des Ponts et Chaussées and has been fully described in the textbooks of that institution which have been published since 1899.

The assertion of the author that he would improve the project adopted by straightening the lower reaches of the river, indicates a failure to appreciate the principles governing this method of river regulation. He is proposing to substitute the German method of river regulation which the Italians (as he states) have abandoned, and is re-opening a discussion which has agitated river hydraulic engineers in Europe for many years, and, at present (1928), receives little support even in Germany.

Humphreys and Abbot demonstrated\* that river-shortening led to a lowering of the low-water pools above a cut-off, and to an elevating of the river bed below. M. Gerardin was the first to recognize the injurious effects of such flattening of the slopes on the river's regimen, and to show the necessity of maintaining the alternation of pools and bars which Nature has created in a river.

Italian engineers appreciate that navigation would be irreparably ruined if the slopes on the lower river, which are now gentle, were still further reduced, and the slopes on the upper reaches, which are now excessive, increased thereby. They not only maintain the existing bars by giving a curved trace to their works, but they are especially careful to limit the river contraction so that they will not create a scour on the bars during flood stages. The limitations of the height of their works to 1 m. above low water is not primarily to reduce flood heights, but rather to invite a fill on bars during a rise in the river. When the river falls, the water is directed along predetermined lines so as to create a channel through the bar which will have the depth desired at all stages. It is for that reason that they have adopted the parabolic curve in their trace.

The extensive use of the waters of the Po for irrigation has rendered the problem more difficult than that occurring on the Upper Mississippi or on the Missouri. The curvature which the bank naturally assumes has, therefore, been more generally utilized in improving the rivers of the United States; and less care has been taken to give a prescribed slope to the contracting dikes.

It is noted that sand dikes and training walls used on the Po are approved by the author. Similar sand dikes have been extensively used by the U. S. Army Engineers in recent years on the Upper Mississippi, and have been equally successful on that river, although they are confined to the convex side of bends.

Permeable dikes were also tried experimentally on the Upper Mississippi more than forty years ago, but brush mattress dams were substituted finally because the river in its upper reaches carries little sediment in suspension even during floods. Below the mouth of the Missouri they have been eminently successful, although it was necessary to give them much greater strength than those described on the Po. In recent years, concrete piles have

\* "Report upon the Physics and Hydraulics of the Mississippi River," 1861.

been quite generally substituted for those of wood, between the mouth of the Missouri River and Cairo, Ill.

The general dimensions of the levees on the River Po were known to the Mississippi River Commission before the existing levee section for that river was adopted, and the sections developed by the Germans on the Rhine and by the French on the Loire were also studied. European levees have generally a greater width of crown and less width at the base than the Mississippi River levees, due principally to the fact that European levees are used extensively as roadways.

Formerly, the usual road of the Southern States consisted of undrained soil without ballast which was nearly impassable during rainy weather. It would have been the height of folly to have permitted the tops of levees to be converted into a similar quagmire by the passage of vehicles over them. It was recognized moreover that the ultimate height of levees had not been definitely determined, and that, if macadam roads were constructed at the low grades then existing, they would have to be rebuilt from time to time. The wisdom of the decision is forcibly illustrated by the results of the flood of 1927. Every road which might have been in existence on the tops of levees would now require reconstruction.

The Commission therefore decided to give to the levee such a form as would offer the maximum resistance against water pressure, with the most economical movement of the earth which formed it. This incidentally created a banquette on which a road could be located whenever the progress in road building reached the stage that the road surface was protected from abrasion. The minimum requirements were a width of crown of 8 ft., and a width of base equal to ten times the probable head of water against the levee. These dimensions were not based on laboratory tests, but on observations of the resistance of the average soil of the Mississippi Valley to filtration. In many localities, not only in the valley of the Mississippi, but also in the valley of the Po, soil is found which is so porous that levees of the dimensions here given are unsafe, but when the muck ditch reveals such a soil, the levee engineers simply enlarge the section by flattening the slopes.

From the writer's inspection of the Po Valley, he gained the impression that the second line of levees were irrigation ditches in which water is carried at considerable heights above the general surface of the ground. He would not, however, question a statement by an authority as competent as Senator Luigi. He suggests nevertheless that a second line at the same elevation would exceed in cost that of one along the river bank, since the ground of an alluvial valley slopes away from the river. The financial condition of Italy hardly justifies such a luxury.

If the space between the two levee lines is allowed to fill during a rise of the river, it will materially reduce flood heights. Whatever may be the attitude of the farmers of Lombardy, the writer is convinced that the planters along the Mississippi River would never consent to such a proceeding. There are double lines of levees along certain sections of the Rhine, but they conform to the conditions shown on Fig. 10, a front line overflowed at medium stages

and a controlling line to regulate extreme floods. The writer has seen a statement in a German publication that this peculiar construction was adopted as a compromise measure to satisfy owners of vineyards who had a theory that the restriction of floods to the front line of levees would have an injurious effect on the grape crop of the adjoining hills.

Science would be greatly benefited if the Treasury of the United States could afford the expenditure and Congress would authorize the establishment of rain gauges throughout this country at as frequent intervals as in the Po Valley. Such data would be extremely valuable for determining the volume of water which causes a flood, when time has been afforded to assemble and digest them; but as a means of flood prediction they would be practically useless. A flood would have passed before a central office could have computed the percentage of flow that would reach the river. The method adopted by the U. S. Weather Bureau for determining flood heights by gauge readings on the tributaries is far more practicable and also more accurate, because it measures the run-off and avoids the necessity of computing the quantity of water evaporated and absorbed by the soil. The flood predictions of the Weather Bureau compare most favorably with those of European nations.

A marked advance in flood prediction was also made by U. S. Army Engineers during the flood of 1927 in the Mississippi River. The determination of the height that the water would attain in the area flooded by crevasses, was of inestimable value to Secretary Hoover in his efforts to rescue flood sufferers, particularly the work of Capt. Lewis A. Pick in the valleys of the Teche and Atchafalaya Rivers.

The observations at Pontelagoscuro accurately determine the quantity of material carried in suspension by the River Po at different stages. They however merely supplement the work of the Mississippi River Commission and of U. S. Army Engineers in the investigation of the flow of sediment in streams. The observations on the Mississippi River not only trace the flow of material in suspension from its source in the tributaries to its deposition in the Gulf of Mexico, but also measure the quantity of material moving along the river bed in sand waves. Furthermore, they indicate the effect of slope, curvature, and discharge on the height and permanency of sand-bars, and the relation of caving banks to turbidity.

The author invites attention to the employment of civil instead of military engineers in improving the rivers and harbors of Italy, but he fails to recognize that the Italian civil engineers are taught the fundamental principles of the science of river hydraulics in the various engineering schools which he enumerates, while the Italian Army Engineer does not have such instruction. In the United States, conditions are reversed. The U. S. Army Engineer is taught at least the rudiments of the science at the Army School at Fort Humphreys, while it is very generally ignored in the various engineering colleges of the country. The assistant engineers who have been employed and frequently have been instructed by the Army Officer are the only other body of engineers who have had practical experience with the problems which arise in the improvement of rivers and harbors in the United States.

The author will be of great service to American engineers if he succeeds in his efforts to persuade Italian engineers to translate into English, their knowledge of river hydraulics. With such information available, it is even possible that it will be unnecessary to establish a laboratory in Washington for the purpose of rediscovering principles known in Italy for centuries and now taught in the ordinary textbooks of the engineering schools of Europe.

OREN REED,\* ASSOC. M. AM. SOC. C. E. (by letter).—With the 1927 flood on the Mississippi River as a reminder, American hydraulic engineers will welcome the author's excellent description of the flood problems of the River Po in Italy. For centuries various methods have been tried in an effort to control the flood flow of the Po, with only partial success. As their knowledge of river behavior has become more complete, the Italian engineers have been able to lessen the damage from floods. Certain practices, which have been proved by long experience to be wise, could be adopted with profit by American engineers.

One point which was not mentioned by the author is the influence of lakes, either natural or artificial, in reducing flood flow. As is shown in Fig. 1, the south slope of the Alps receives the largest precipitation of the Po water-shed. This drainage is partly regulated by large lakes—Garda, Iseo, Como, Lugano, and Maggiore. The regulating effect of these lakes would be very great without any artificial control. Lake Maggiore has an area of about 83 sq. miles. A record of its maximum and minimum water levels shows that the yearly variation is from 6 to 16 ft.† This large annual variation would indicate that in a wet year the lake had temporarily retained a large volume of water which would materially affect the flood discharge of the Lower Po.

The effect of natural retention in lakes was clearly illustrated in September, 1927, by Lake Constance, which is located on the German-Swiss border. The head-waters of the Rhine River in Switzerland were swollen by a severe two-day storm in the last days of September, 1927. The quantity of water carried by the Rhine above Lake Constance on September 25 and 26, 1927, was the greatest yet observed. The flow into Lake Constance from the Rhine on September 25 reached a maximum of 81 300 sec-ft. The total inflow into the lake was 148 500 sec-ft. The maximum outflow occurred on September 29, and was only 29 700 sec-ft.‡

In Norway, investigations have recently been completed to establish a comprehensive plan for flood regulation on the Skien River. This study was prompted by a flood of high intensity in June, 1927, which caused great property loss. The communities affected by the high water, appointed committees for the purpose of perfecting a plan for preventing a similar catastrophe in the future. The technical study was under the direction of Christian Raestad.

The Skien is the third largest water-shed in Norway and has a drainage area of 4 060 sq. miles at the City of Skien, which is about six miles from

\* Care, San Joaquin Light & Power Corporation, Fresno, Calif.

† Schweizerische Wasserversorgung, February, 1928, p. 21.

‡ Loc. cit., p. 17.

the North Sea. Nearly all the area is mountainous and includes numerous lakes and fjords. The head-waters flow from a plateau region, a large part of which is marsh land.

The Skien District is one of the most important in Norway. It has long been noted as a timber-producing district. "Norsk Hydro" (the Norwegian Electric Company) is located in the central part of the water-shed about 65 miles from the ocean. This Company, the leading industrial concern in Norway, uses hydro-electric power for the fixation of atmospheric nitrogen. The total plant capacity controlled by Norsk Hydro amounts to about 260 000 kw.

Dams have been constructed at the outlets of a number of large lakes in the Skien water-shed for the purpose of regulating the flow for power and for the floating of timber. Most of these regulated lakes are in the upper part of the water-shed. The most important ones are: Mos Lake, 597 000 acre-ft.; Maar Lake, 183 000 acre-ft.; and Tinn Lake, 159 000 acre-ft.

Authentic records of floods on the Skien River begin about 1645. Serious floods have occurred at frequent intervals, but none has caused as much property damage as the flood of 1927. The banks of the river had been encroached upon in recent years by industries and private interests. After the regulation of Mos and Maar Lakes the low-lying areas were built upon, for it was expected that flood levels would be reduced. The 1927 flood was caused by heavy precipitation, augmented by melting snow, on the lower part of the water-shed. Regulation of the upper lakes decreased the possible flood, because no water was released from Mos Lake during the flood period.

Floods on the Skien have usually occurred in the late spring and are caused, as in 1927, by heavy precipitation and melting snow. There have been, however, many autumn floods. The highest recorded flood at the City of Skien was in June, 1927, and amounted to about 106 000 sec-ft., or 26.2 sec-ft. per sq. mile of total area.

The recommendations of the Committee appointed in 1927 were: (a) To increase the capacity of the stream at critical points; and (b) to decrease the flood flow by further regulation of natural lakes.

At the City of Skien and at Skot Fall, crib dams serve for diversion to low-head power plants. During flood periods these dams materially raise the water level. It is proposed to remove these crib dams and construct new structures, regulating the flow by means of roller or sector gates. During floods, the gates would be opened and would present no obstruction to the flow. At certain points considerable dredging will be necessary to obtain sufficient channel capacity for the maximum possible flood.

The flow in the upper part of the drainage basin is regulated at present in Mos, Maar, and Tinn Lakes. Additional regulation is planned for the middle section of the water-shed at Lake Totak and at Sundsbarn. It is thought that the maximum probable flood can be economically decreased about 21 000 sec-ft. by the proper regulation of these lakes. This would be about 20% of the 1927 flood.

By regulation more of the flow can be made useful for industries and power plants. This will be a valuable feature, although the chief purpose

of the work will be a reduction of flood flow. It is thought that the work can be financed by assessments on the communities and industries benefited without any aid from the State. For reasons of economy, it will be necessary to do the work in two or more steps.

JOHN P. HOGAN,\* M. AM. SOC. C. E.—The author has called attention to the fact that there really is a flood-control proposition that is being studied in a scientific manner. This is particularly appropriate at a time when, during the past year or year and one-half (1927-28) engineers have been attempting to handle a flood-control proposition partly on a political basis and partly on a sentimental basis. The speaker refers, of course, to the Mississippi River.

It would seem that in order to provide flood protection, the first and foremost thing would be the necessity of determining what the maximum flood might be. Allen Hazen, M. Am. Soc. C. E., has given a very great contribution to this subject† which, of course, is as applicable to flood control as it is to river regulation. Nevertheless, the law of probabilities will never foretell the maximum flood that will occur. It will only predict the probability of the occurrence of a flood. It may be known that a certain flood will occur once in 100 years, once in 20 years, or once in 10 years, but it will not be possible to predict that perhaps to-morrow, or next year, there is going to be the flood which is due once in 10 000 years. It would seem to be axiomatic that absolute and positive flood protection by completely confining the waters of a river within a narrow channel is not economically feasible, and there is considerable doubt as to whether it is practically possible.

Without any further study and with very indefinite knowledge on the subject, efforts have been made to pass a blanket resolution providing indefinite sums of money to control the Mississippi River. There has been absolutely no effort whatever made to accompany the plans for control with any economic study, to determine whether such a regulation is advisable. It certainly is evident that it does not pay to spend \$1 000 000 000 to save \$100 000 000.

It would also seem evident that the river must have a channel with certain marginal districts of land subject to periodic flooding, as Mr. Freeman has shown in regard to the Arno. It would seem that the first process in determining a reasonable plan of regulation for the Mississippi River would be an estimate of the present value of the land affected and its prospective value. A determination could be made, on that basis, of the present and future methods that should be used either to reclaim or preserve from flood at the present time the maximum acreage of land which might economically be reclaimed, and to provide for certain future measures that could be applied if and when the reclaimed land becomes sufficiently valuable to warrant it. Further large expenditures might be justified on the broad

\* (Parsons, Klapp, Brinckerhoff and Douglas), New York, N. Y.

† *Transactions, Am. Soc. C. E.*, Vol. LXXVII (1914), p. 1539.

grounds of public welfare, but the speaker believes that the economic survey should be the first step.

Land owners have been crowding into the lowlands for the past 50 or 100 years as land became more valuable. They have been filling up the channels which were formerly open to the river in time of flood. It would seem that it is about time, as far as a river like the Mississippi is concerned, to take stock, and to find what should be reclaimed and preserved either in the present or in the future.

In presenting this view of flood control on the River Po in Italy, Mr. Freeman has done a real service.

WILLIAM B. GREGORY,\* M. AM. SOC. C. E.—The speaker is very much pleased with Mr. Freeman's paper. It is a splendid example of the ways in which hydraulic information should be gathered and applied to a problem such as that of the Po.

There are many people in New Orleans, La., who think because they have lived on the banks of the Mississippi River and have seen it all their lives, and because their fathers saw it all their lives, that they know all about it; and one of the most common fallacies is the belief that the bed of the river is rising. They have seen the levees rise as the years go by; in fact, in the thirty years that the speaker has lived in New Orleans the levees in the front of the city have been raised about 6 ft.; and, of course, people who are not acquainted with hydraulic laws jump to the conclusion that the bed of the river is rising, which is not true. What Mr. Freeman has emphasized in connection with the Po, is also true of the Mississippi; namely, that it is not scouring out a deeper bed, as was hoped years ago.

The Mississippi River Commission began with the idea that confining the river within levees would scour out a deeper channel and improve that channel. In an address at Memphis, Tenn., C. McD. Townsend, M. Am. Soc. C. E., stated that while that might be true extending over a long period of time, it would be of more interest to the people who will occupy the valley in the Twenty-fifth Century than to those who live there now.

Incidentally, Colonel Townsend has stated† that the Mississippi River Commission had every bit of information that is necessary for the control of that river, and all that needs to be done for it in the future.

JOHN R. SLATTERY,‡ M. AM. SOC. C. E.—It seems always of great importance to bring out the fact that the bed of the Po and the bed of the Mississippi have not risen. At least, if the bed of the Mississippi has risen, it has been at so slow a rate that as far as the engineers of the present day are concerned it need not be considered. That misleading observation of the old priest traveling along the Po has caused more sorrow and grief to engineers engaged in flood control on alluvial streams than almost any other fallacy.

A few years ago, C. McD. Townsend, M. Am. Soc. C. E., made a most exhaustive study of the Italian records. He did not read or speak the language

\* Prof. of Experimental Eng., Tulane Univ., New Orleans, La.

† *The Military Engineer*, March-April, 1928, p. 93.

‡ Deputy Chf. Engr., Board of Transportation of the City of New York, New York, N. Y.

before that time, but he studied enough Italian to delve into the records of the Po River, and his paper on that subject was one of the most conclusive that has been written. The paper was not published; it is in the archives of the Mississippi River Commission.

Spur-dikes or retards have been tried on many rivers in this country as well as in Europe. The great trouble with that system of improvement seems to be that, while something is accomplished, the end sought is never fully realized. A system of spur-dikes to produce a channel 9 ft. deep may be designed. The system is completed, some improvement results, but the desired 9-ft. channel is rarely, if ever, obtained. An elaborate system of dikes of that character has been under construction above Cairo, Ill., on the Mississippi River, for a number of years and has produced a marked improvement.

In early years some attempt was made at Lake Providence, or in the Providence Reach and the Plum Point Reach, at river control, and it was more or less successful. It was abandoned because of the great expense and because through the development of dredging it was unquestionably cheaper to maintain the necessary depth by this method than by a system of permanent structures.

The flood-fighting methods on the Po, mentioned by Mr. Freeman, are quite similar to those used on the Mississippi. In fact, those officers who have been engaged on the Mississippi are made to study quite thoroughly the history of the Po as well as of all other similar rivers. Many plans are thought to be new when as a matter of fact they have been tried and failed. The Mississippi River Commission has been liberal in providing money for the investigation and trial of really new ideas, but has properly set its face against wasting money in investigation of plans already thoroughly tried out without satisfactory results.

One of the great difficulties on the Mississippi has been the divided control. In the 1916 flood the speaker saw the gauge at Cairo gradually rising, and about three weeks before the crest reached Vicksburg, Miss., it was realized that the flood that year would be the highest that had ever been known. It was evident at that time that a severe fight was on hand. It was evident, also, that certain stretches of levees would have to be built up with sand bags.

As the flood advanced, the necessity of carefully guarding the levee was realized. Most levee problems (if the levee is not overtopped), can be controlled, provided warning is received in sufficient time and that the proper supply measures are taken at the beginning. The speaker, therefore, through the newspapers of Greenville, Vicksburg, and the small towns that published papers, urged all owners having plantations facing on the levee system to undertake the patrolling of their own levees.

They all have large numbers of negroes; there is no scarcity of help. These people are practically carried through the winter season anyway by the planters for whom they work. There was immediate and violent opposition on the part of one levee official because of what he seemed to think was the usurpation of some of his authority, and it took a great deal of diplomacy before he was finally mollified and brought to co-operate in securing the proper guarding of that levee system.

Millions of sacks that year were purchased, 6 000 000 in that one district, and distributed to various warehouses along the river. The plant of the district consisted of 5 towboats and about 80 barges. Those were distributed at strategic points along the river. Barges loaded with gravel and lumber were stored in the lower reaches where the back-water up the Yazoo Valley attains almost the same height on the levee as the water on the outside.

The levee line was carefully watched; a warning was sent of a boil at this point; a sloughing bank at that point; water lapping over the levee at another point; and within a few hours it was possible to move men and supplies to any point on that river, and that was the way that the levee system was held. At three o'clock one morning a steamboat captain telephoned that the water was running over the levee a little north of Vicksburg for a distance of about 5 miles. At seven o'clock the next morning barges of gravel and sand bags were at that particular point. The back-water was so high that no material could be obtained from the levee itself. Nevertheless, if the levee were lost, it meant an extension of the flood a number of miles up the river. The actual difference between the level of the back-water and the water in the river at that point was about 5 ft. It took a week of fighting, but at the end of the first day there was a line of sacks above the flood, and that flood was followed up until it crested by adding line after line of sand bags.

Some of the methods that are now suggested for the improvement of the river have received most careful consideration in former years. One reason why they have never been adopted has been the strong local opposition to anything but levees.

The Cypress Creek Gap was closed while the speaker was in Vicksburg, or rather, it was started. It was realized that the closing of that gap would immediately raise the height of floods for some distance below the mouth of the Arkansas, because the closure cut off an enormous reservoir in Arkansas and Louisiana. Much of the land in this region was not particularly valuable; a great deal of it was not and probably is not to-day under cultivation; a great deal of it was wooded; there were many cotton plantations so infested with boll weevil that cultivation had ceased. At the same time the local pressure to stop the overflow, which took place at a stage of 49 ft. at Arkansas City, was so great that the Mississippi Commission had to close the gap. The 1922 flood confirmed, to within 1 ft., calculations made in 1916, as to the effect, of closing that gap, on river stages at Arkansas City and vicinity.

The overflows are not always an unmitigated curse. No planter wants to see his land overflowed; but many a planter, after a crevasse has occurred, finds that the following year the increased fertility of the soil more than offsets his loss for the one year of flood. It sometimes happens that, instead of coating his plantation with a film of rich silt, sand is carried in and his plantation is ruined for years to come, so it is a gamble. There are parts of the Mississippi Valley to-day that would be greatly benefited if they could be overflowed. The soil has been worn out, and the rich plantations that once existed there cannot now pay expenses.

The Po and the Mississippi are near relatives, but the levee section on the Mississippi is quite different. There has long been consideration given to

the desirability of putting a road on these levees. The river slopes on the Mississippi levees are 1 on 3, or, in certain soils, 1 on 4. The top width is 8 ft. The slope down to the banquette on the land side is 1 on 3. The banquette is from 8 to 12 ft. below the crest, and varies in width from 20 to 40 ft., with a slope of 1 on 6. The lower slope on the land side is about 1 on 4. This heavier section is necessary, as Mr. Freeman pointed out, because of the long period that the water stays high; and on the Mississippi those fighting the floods do not feel safe until the water has fallen about 10 ft. below the crest of the levees. Even after the water starts to fall, there is still danger of these levees failing with the reduced head through sloughing.

On the matter of cut-offs, or the straightening of rivers, in this country the general rule is not to straighten a river except where streams, such as those in Florida, have a very slight slope. There, the streams are materially shortened to their great advantage. On the Mississippi, however, every effort is made to prevent cut-offs. Above Greenville, for instance, there is a long bend around a long point of land. It was 5 miles around this point and only about 2 400 ft. across it. A cut-off would have shortened the river about 4 miles.

The river began to cut channels across the point, and an attempt was made to fill them by permeable dikes. They were not successful. It was impossible to induce those channels to fill. The banks were heavily revetted along the upper side of the point, but some signs of failure were noted. It was recognized that if the neck was cut through, at least one-half the levee system for perhaps 50 miles below would go as a result of the bank caving that would follow from the excessive currents that would exist until such time as the river re-adjusted its slope.

An earthen dike about 3 or 4 miles long was built from the levee system out to near the point. Straightening the Mississippi is not to be thought of unless the banks and bottom for many miles above and below cut-offs can be adequately protected against scour. To any one familiar with conditions on the Mississippi above Baton Rouge, La., the problem of preparing the bed to carry the river safely at a greater slope, comes within the realm of economical impossibilities.

ARTHUR P. DAVIS,\* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The River Po presents unusual opportunities for the study of river hydraulics, not only on account of its opportunities of physical conditions, but also due to the long history of its use and modification by human agencies. Mr. Freeman's paper is of great interest and shows industrious research into the history and literature of this river.

The typical large river system, of which many examples can be found in the world, is a collection of drainage from high or mountainous regions, which flows to the sea, eroding its channels in the upper reaches and depositing the eroded material at its mouth. In the course of hundreds of thousands, or perhaps millions, of years, the basin is lowered some hundreds or thousands of feet by the influence of the waters of this river system. Where the climate is humid and the rainfall considerable, the hilltops are weathered and disinte-

\* Chf. Cons. Engr., Sredazrodhoz, Tashkent, Turkestan, Union of Socialist Soviet Republics.

grated by the action of the rain and frost, and the tendency is to produce a rounded topography such as that seen in the Appalachian Mountains, and in the main in the Rocky Mountain System as well. If the river through its course carries its load of water and sediment through an arid region where the surface weathering is slight and where the declivity of the river permits rapid erosion, deep and narrow canyons may be produced, as in the Colorado System of the Southwest.

Throughout the history of such a river system, the forces of Nature are actively at work degrading the topography toward the condition known by geologists as "base level", and, if not interfered with, the entire basin with lapse of time, would be reduced to a "base level" or a region so flat that any movement of water thereon would be so sluggish as to produce no erosion. Limited areas of such base levels occur near the mouth of every large deltaic stream, such as Southern Louisiana on the Mississippi, and the great delta of peat land area near the junction of the Sacramento and San Joaquin Rivers in California.

Whether the river has declivity enough to produce erosive velocities, it continues to erode its channel until this is reduced to an elevation such that the fall to the sea is insufficient to produce such velocity. The slope that is necessary varies, of course, with the quantity of water flowing, the larger quantities producing higher velocities, so that there is a critical stage in some part of such rivers where the channel has a tendency to erode at high stages and to refill at low stages.

The work of the river through the centuries, bringing down its load of sediment, builds a larger and larger delta at its mouth through which the stream meanders a sluggish course at ordinary stages, depositing the load that it has brought from the mountains. Many interesting examples of this may be cited.

The Yangtze-Kiang in China has advanced its mouth thirty miles into the Yellow Sea by progressive delta building during historic times. The great deltas of the Mississippi and Sacramento Rivers are well known in detail. The Colorado built a delta at its mouth extending from the California line entirely across the Gulf of California, severing the head of the Gulf from the main body and forming thereby an inland sea which evaporated and formed the Imperial Valley lying below sea level, with a strongly saline lake in the bottom. This delta of the Colorado River has been built to an elevation of 40 ft. above sea level at its summit and reaches north and south nearly 100 miles.

As the mouth of such a river advances into the sea, the increased length causes a reduction of the gradient of the stream which is emphasized also by the reduction of the elevations higher up by erosion. This decrease of gradient deprives the river of part of its carrying power and causes the deposit of a portion of its sediment farther and farther up stream; so that for some distance up stream from its mouth there is a gradual tendency to the upbuilding of its channel. As this upbuilding progresses, the river bed rises and creates a tendency to overflow which is characteristic of every such river throughout its lower course. As the river begins to overflow during the flood, the water

overflowing the banks is checked in velocity where it encounters the obstruction of vegetation and shallow depths, and immediately deposits the coarser materials it is carrying. This tends to build up the immediate banks of the river, while the partly clarified water spreads out over the valley and deposits a thinner layer of sediment. Thus is formed the characteristic topography of a river channel as it approaches the base level condition, where the banks of the river are higher than the grounds immediately back of them and there is a tendency for the river to run on a ridge as illustrated in the paper (see Fig. 13).

This unstable condition cannot continue, however, and some time at flood the river breaks the banks and flows through the lower country in a new channel where, in time, the same process is repeated; and thus the river swings back and forth in the course of centuries and builds up a broad alluvial valley to an extent sufficient to maintain such velocities as will carry a portion of its sediment to the sea. Thus, the combination of conditions involves the processes, (a) the degrading influence throughout the mountainous regions of the stream near its head-waters; (b) the erosion of its channel through the upper course; (c) the building of a broad alluvial valley through its lower course; and (d) the extension of the delta at its mouth into the sea.

The writer visited the Po Valley in 1911 and examined its largest irrigation system, and by these observations and the impressions produced by the literature on the subject, concluded that the Po River was typical of the conditions described. It is probably one of the best types to be found, rising as it does in the lofty Alps and Apennines with their high precipitation and heavy slopes; it has wide valleys with deep alluvial soil throughout its lower courses, and a characteristically large delta at its multiple mouths.

As the Po River still comes from the high Alps and Apennines, affording abundant precipitation and abundant gradient, erosion of the channels through the mountainous regions must still be in active progress, and this material must be deposited either at the mouth of the river, or in the valley, or both.

It is interesting therefore to find that, in the "Introduction", the author makes the following statement:

"Flood heights certainly have increased, but the best data available show that meanwhile the bed of the main channel has not been raised."

This statement is doubtless based on the report which the author quotes from the Ministry of Public Works, as follows:

"As seen from the said studies of the Hydrographic Office of the Po and from the hydrometric observations of the Po for a century, it is evident that the bed of the river presents no tendency to a progressive rising."

This conclusion, in view of the surrounding facts, is interesting, for if no sediment is deposited in the river bed, it must all be carried to its mouth and deposited in the Adriatic where it would lengthen the course of the river and progressively reduce its gradient.

The confinement of the river between dikes would prevent the deposit of sediment over the floor of the valley and confine it either to the river bed or to the delta in the Adriatic and would actually accelerate the growth

of the delta and the consequent rise of the river bed. This tendency could be postponed and even for a time it could be reversed by straightening the river channel, which would reduce its effective length and thereby increase its gradient; and this, in turn, would increase its velocity and prevent deposits in the river bed. If such were the case, the eroded material from the mountains would travel to the sea and the growth of the delta would be accelerated and, in time, would add to the length of the river sufficiently to counteract the shortening produced by straightening. This seems to be the most plausible explanation of the apparent anomaly already noted. Mr. Freeman's opinion on this explanation would be interesting and valuable.

If this artificial straightening has not occurred, what then is the explanation of the fact that the building up of the river bed, which has been proceeding "during hundreds of thousands of years by the sand and mud eroded from the mountain slopes", has recently stopped?

Whether the bed of the Po, or of the Mississippi, or of the Yellow River, or of any other deltaic stream, has been built to an elevation higher than the adjacent country, is a question only of speed and of quantity. Hydrologists should not lose sight of the fact that all such rivers are eroding material from their upper reaches, bringing it down into the lower valleys where it is all consumed in enlarging its delta, lengthening its course, or building up its valley and river bed, or both.

If the river is confined so that it cannot deposit its sediment in the broad valley, all this sediment must then be utilized in building up the river bed or extending the delta, or both. In the long run both must occur, else what is to become of this sediment?

The Rio Grande and some other streams have varied this program temporarily due to the operations of Man. In the case of the Rio Grande, the head-waters were consumed largely in the irrigation of upper valleys and the steady flow of considerable quantities of water which formerly occurred have been largely stopped. This same flow consists mostly of clear water resulting from melting snow, and the reduction of its volume and the shortening of the season of its discharge by consumption above have deprived the river of a large proportion of its carrying capacity through the middle and lower reaches. The result is that the torrential tributaries which bring their loads of sand and gravel to the valley during sudden storms, build up their deltas faster than the main stream can carry them away and the reduction of the summer flow has greatly accelerated this process. Some parts of the bed of the Rio Grande have risen during the past fifty years from 2 to 12 ft. by actual levels, which is doubtless much faster than the rate of rise before the water was diverted at various points.

The most complete plan for the control of the floods of the Lower Colorado involves not only the regulation of the river through large storage works, but the straightening of its channel in the lower course for a distance of about 100 miles above its mouth. It is believed that it will be practicable to shorten this stretch of the river 30 or 40% by confining it between straight dikes set as close together as conditions permit and preventing the river from meandering. This, of course, will add greatly to the effective gradient of this section

of the river and will cause it, for a long time to come, to erode its channel and thus remove the tendency to overflow. This effect, however, can be only temporary and will eventually be overcome by the deposits in the delta, the lengthening of the channel, and the loss of gradient resulting therefrom.

Such operations, of course, would result in a condition in which the river in this section would present "no tendency to a progressive rising", as reported by the Hydrographic Office of the Po. This would not set aside the general principle that these alluvial streams have been for thousands of years, and will be in the future, progressively building up their channels and their valleys and extending their deltas with the sediment brought down from the mountains; nor the further fact that if the stream is prevented by dikes from depositing this sediment over the wide valley, it will greatly increase the amount that must be devoted to extending the delta and building up the river channel, unless the sediment is stored above, which is not the case on the Po.

These tendencies may be modified by the storage of sediment in reservoirs near the head-waters; by the diversion of water for irrigation; and by the straightening of the channels; or, perhaps, by some other operations of Man. The effect of these operations is necessarily temporary, geologically speaking, and eventually the time must come when the river will resume building up its bed.

It would be interesting to know just what operations of Man have modified these natural tendencies in the Po Valley, and how permanent they may be.

G. DE THIERRY,\* Esq. (by letter).—This paper gives an excellent picture of the development of the regulation of a river on the banks of which the cradle of hydraulics has stood.

On the Po, as on all other rivers, the first works erected by the hand of Man were for the purpose of protection against the dangers incident to high water. The attempt to protect as much of the adjoining land as possible from floods has led, on the Po as well as elsewhere, to a narrowing of the river channel which doubtless has constituted in places an obstacle to the free run-off of high water. The attempt to remove these obstacles subsequently has met with opposition which has been the stronger, the further the utilization of the land behind the levees has progressed. Such levees can naturally occasion a rise in high-water levels, so that frequently erroneous conclusions regarding the raising of the river bed are drawn from this phenomenon. Particularly valuable is the clear statement that neither on the Po nor on the Yellow River in China can any raising of the river bed be traced to the effect of levees.

There is only a single particularly characteristic case of the raising of the bed of a river known to the writer. For decades it has been known that on the section of the Rhine above the Bodensee, opposite the Principality of Lichtenstein, a rise in the river bed amounting to 2 cm. yearly exists. The Rhine is diked on both sides along this section; but it would be a serious error to attribute the rise in the river bed to these parallel levees. The building of control structures along the mountain streams above this section of the Rhine

\* Berlin, Germany.

is still far behind what it should be because of the very considerable cost involved. Consequently, after heavy rainfalls, or a sudden melting of snow, these mountain streams bring down enormous quantities of gravel which are in continual motion and which the river cannot digest. It is quite possible that the effect of the cut-offs and the new outlet into the Bodensee will extend far enough up stream to prevent the deposit of this gravel. In any event it will be a long time before the effect in this part of the river will be demonstrable. The creation of a new outlet into the Baltic Sea has produced a far-reaching reduction in the level of the highest water on the lower reaches of the Vistula River. The increase in the velocity involved in the shortening of the stream has brought with it a lowering of the river bed, so that on the Rhine above the Bodensee a similar effect is to be expected.

However, the Rhine below Basel, Switzerland, has proved that a long period of time must elapse before a verdict can be given. A century ago, at the instigation of Oberst Tulla, numerous cut-offs were undertaken between Basel and the Hesse-Prussian border, reducing the length of the river to 81 km. Enormous quantities of gravel were thereby set in motion. On the upper part of this stretch of river the deepening of the bed exceeded 3 m.; farther down stream, the bed was raised. Although this progressive change in the river bed dates back fully a century, it is by no means finished, and it is scarcely possible to predict when it will come to an end. However, in this case again, the cause is not to be traced back to levees.

During the writer's visit to the United States in 1927, he observed repeatedly that the Army engineers considered that there was no object in building a hydraulic laboratory. They contend that the accumulated results of experience gained by working with Nature itself are more valuable than the study of natural processes in the laboratory. They thus overlook the fact that most of the processes in the realm of hydraulics are of an extremely complicated nature, and that the observation of particular phenomena in Nature permits only in the rarest instances an analysis of the individual factors which have operated together to produce the phenomena observed. The investigation of cause and effect is the ultimate goal of science, and the hydraulic engineers in Germany are convinced, after 30 years' experience, that the hydraulic laboratory is an indispensable aid in the development of this science.

River problems are among the most difficult that the hydraulic laboratory is called upon to solve. The river in its natural state is the result of numerous factors, not only of a meteorological, but also of a geological, nature. The processes of flow, the distribution of the flow during the year—not only of the quantity of water corresponding to each stage, but also the duration of a particular flow, which fluctuates from year to year within certain limits—affects the course of the river. Only in the rarest cases is the problem confined to the same kind of geological formation in a river valley. It is quite possible to reproduce a stretch of river which has been accurately examined geologically and to investigate on this the effect of particular structures; but when the results of laboratory tests are to be carried over to Nature, one must always expect that, through accidents, through changes in the nature of the river bed, through snags or sunken vessels which are often invisible to the engineer,

effects are produced which evade all attempts to reproduce them in a model test. Certainly, indications as to the best solution of a particular problem can be obtained through the laboratory, but there is little hope that, with the erection of one or more laboratories, the difficult problem of the Mississippi can be completely solved.

When, at the end of the Nineteenth Century, devastating floods occurred on various German rivers, there was appointed, at the command of the Kaiser, a commission whose function was to investigate the causes of the different flood catastrophes. The results of this investigation, which was conducted with unusual thoroughness, are compiled in a series of works which comprise an imposing library.

Mr. Freeman deals with the question of whether it is more practical to entrust the work to be carried out on the Mississippi to engineers in civil life in place of the existing military organization. This is a matter which must be settled within the United States itself.

The writer believes, however, that the author has made a very important suggestion, the application of which should not be disregarded. The Po, like every other river, is, in effect, a living organism, the study of which requires more than the lifetime of any one man. First, through systematic work, all the data can be brought together to give a unified picture of the organism which the engineer is to attempt to improve. Every interruption in the continuity of this scientific work is injurious. The unified and complete picture which Mr. Freeman has given makes it obvious that in more than a century of systematic work the fundamental facts for the investigation of all the factors affecting the formation of the river have been collected and assimilated.

M. GIANDOTTI,\* Esq. (by letter).—This paper describes very well the actual conditions—geo-physical, morphological, and hydraulic—that occur on the River Po.

The tributaries of the Po may be considered as divided into two distinct classes (depending on their origin), namely, Alpine and Apennine. The most important Alpine tributaries are the Ticino, Adda, Oglio, and Mincio Rivers, which flow through Lakes Maggiore, Como, Iseo, and Garda, respectively. This common characteristic of these rivers to form lakes provides a natural settling basin, and the tributaries thus deposit all sediment carried in suspension at these places. Below the lakes the rivers are quite clear and carry only some fine sand and mud, so that the Po receives no sediment from these rivers. The clear water tends, rather, to clean out the bed of the river, even removing some of the sediment brought down from the Apennines. The water-sheds that drain into the Apennine tributaries are almost entirely composed of calcites and argillaceous materials and, therefore, the streams are very turbid. In a manner similar to the Alpine tributaries, the Apennine rivers deposit the heavier material in so-called "expansion beds" which extend up stream from the Bologna-Milan Highway for 50 or 60 km. These beds have a variable width of from 1 km. to about 100 m. and a slope not greater than 5 to 8 per cent. After the heavier material has settled out, the rivers

\* Chf. Insp., Civ. Eng. Dept., Po River, Parma, Italy.

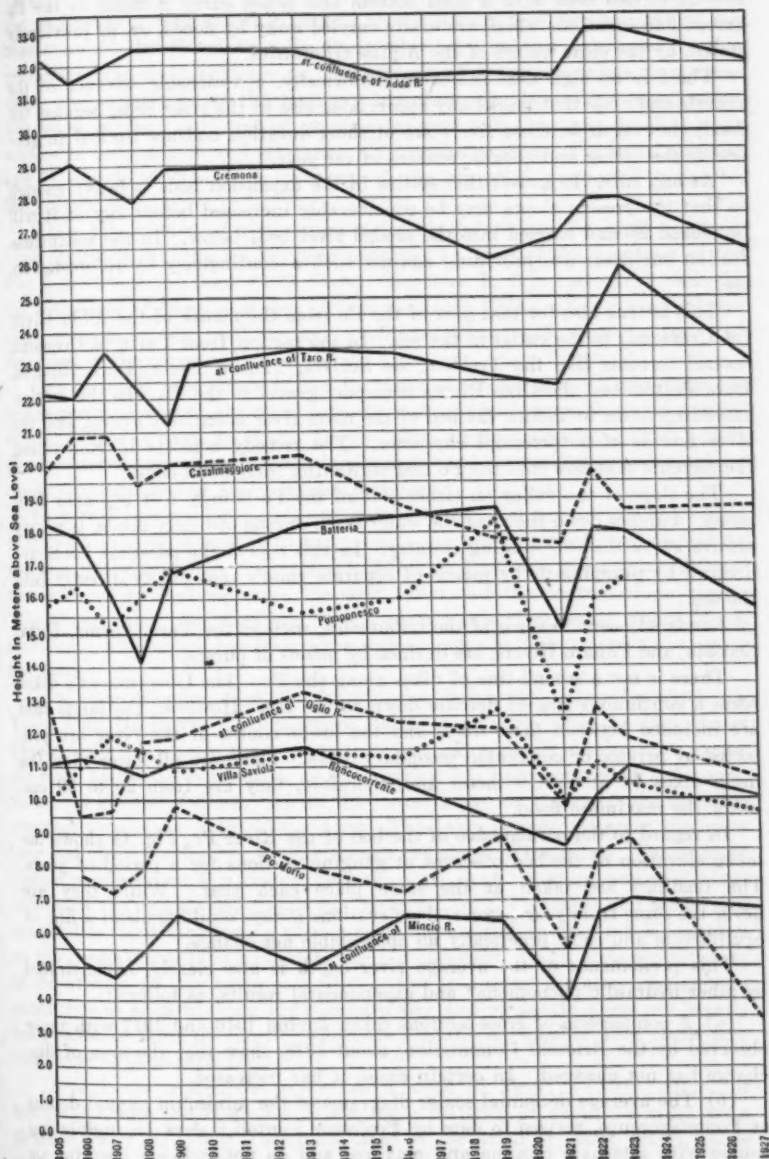

FIG. 14.—CHANGES IN MEAN ELEVATION OF BED OF RIVER PO AT GAUGING STATIONS FROM 1905 TO 1927.

flow in eroded beds with a sand bottom and hence carry nothing to the Po except fine materials which are easily carried away by floods, or, as previously stated, by the clear waters of the Alpine tributaries.

There is no sign that indicates, historically, a noticeable advance of the gravels and none that marks any appreciable rise in the river beds, because the floods that occur in these rivers are of short duration and are limited in general to the spring and autumn seasons of the year.

At any rate, the gravel that settles in the expansion beds is heavy enough so that the present slopes may be considerably increased before any of it will be picked up and carried into the eroded river beds below. In the meantime, Italian engineers are providing against such a contingency by reforestation, etc.

This is true also for that part of the Po from the mouth of the Adda River (at Cremona) to the outlet at the sea. In the section from Turin to Cremona several torrents like the Trebbia, the Scrivia, Tanaro, Sesia, Dora Riparia, Dora Baltea, and the Orco Rivers transport gravel to the Po. In the section extending down to Ticino, the bed of the main river is entirely gravel, and the river flow is of a torrential character. The remedy consists in controlling the torrents that flow into the Po and regulating their delta cones.

The slope of the valley on either side of the Po is only 1 or 2% near Cremona. Farther down the river the water level, during ordinary floods, is nearly always above the surrounding country. In this region the adjacent lands are drained by pumping or by means of separate canals that empty directly into the sea.

Lands adjacent to some of the tributaries, such as the Taro, Parma, Enza, Secchia, and Panaro Rivers, are drained by means of pumps.

There is not a second line of dikes along the Po. The Government's dikes form a continuous line of defense down to the sea. However, the lands that are included between these dikes and the lower course of the river are protected by private or communal secondary dikes. These are all lower than the main dikes by at least a meter and, therefore, they are from 20 to 30 cm. below the maximum flood.

In regard to the permanence of the bed of the River Po, Fig. 14 shows the mean elevation of the bed observed at gauging stations for a period of years. The readings are taken at the same place each year. While they are never the same from year to year, the elevations always oscillate about a line of equilibrium and show practically no appreciable net change.

This permanence of the average river depth is also clearly demonstrated by other hydraulic phenomena\* and experimental results, as follows:

(a) A comparison of cross-sections taken during 1916 and 1917 with those observed by the Briosci Commission, about 1878, show that the area of discharge has not changed. In certain cases, it has increased.

(b) The average decennial scalar diagrams of the minimum annual depths at Pontelagoscuro, revised to date by Professor Fantoli,† show an undulating course with alternate minima and maxima, and do not indicate lowering or raising the level of the river bottom.

† "The Po in the Ephemerides of a Century."

R. D. GOODRICH,\* M. Am. Soc. C. E. (by letter).—The author has given the profession a very valuable résumé of the history and development of the regulation of the River Po. To those who have become interested in this particular branch of engineering, the records of the observations, investigations, and experience of the eminent engineers who have been engaged on this work in Italy, are not of passing interest only, but are invaluable as sources of information and reference. Hence the paper is of unusual interest and is especially timely on account of the situation connected with the Mississippi River.

While the science of river engineering doubtless had its birth in Italy some centuries ago, the art has been practiced in some of the countries of the Far East for more than 2 000 years. Nowhere is this more true than in the Provinces of Shantung and Chihli, in North China. Some comparisons and contrasts of the practice and conditions there with those in Italy, as described in the paper, will be of value.

One of the largest rivers of the Province of Chihli is the Yung Ting Ho which presents one of the most difficult and interesting problems of regulation and flood control in North China. The single exception is the Yellow River which is, of course, a much larger and longer stream with many unique conditions introducing many special problems.

In 1918 a commission, of somewhat international character, was organized by the Chinese Government to carry out some much needed flood-protection and regulation works on the rivers of Chihli, and to survey the general situation and recommend measures for flood relief and the control of its rivers. This Commission therefore has been studying this river, with others, for a short time, although it has been more or less under human control for at least 500 years.

It is about 80 miles from the foothills just below the canyon by which the Yung Ting Ho leaves the mountains, to the confluence with the Hai Ho at Tientsin, 30 miles from the present sea coast. Practically no drainage enters the river below the mountains as this portion has been controlled for a long time by a system of dikes. Above the lowest gorge on the river, the effective drainage area is about 18 000 sq. miles. The basin is approximately 200 miles long and about one-half as wide, although the shape is irregular. The average annual precipitation at Tientsin, near the coast, is about 20 in., and at Peking, just below the mountains, it is 24 in. However, on the plateaus and mountains comprising the drainage area of this river, the rainfall is very much less than on the coastal plains; but the data are not sufficient for an accurate estimate of the average for the basin as a whole. For this river, therefore, the general conditions as to rainfall on the coastal plains and mountain areas are exactly the reverse of those on the Po, while the amount is probably only about one-third that in Northern Italy.

Through the gorge, the river has a slope of about 1 : 300. Above, it meanders across the Huai Lai Plain for a distance of about 15 miles on a slope of about 1 : 1 000. This plain is at an elevation of about 720 ft. above sea level. To the north and west, above this plain, the river drains a series of mountain ranges and high plateaus.

\* Prof., Civ. Eng., Coll. of Eng., Univ. of Wyoming, Laramie, Wyo.

Summer is the flood season in North China, with the heaviest storms between July 10 and August 20. However, the disastrous effects of the worst storms may not occur near the coast until the waters which accumulate behind the levees on the plains reach their maximum height. Under present conditions this may not happen until late in September, as in 1917. These great floods, which inundate thousands of square miles of agricultural land, are caused by a succession of typhonic storms. That of July 15 to 17, 1924, produced a maximum discharge of about 176 000 cu. ft. per sec. below the foothills, or about seven-tenths the maximum rate for the Po, in 1917. This is an average run-off for the Yung Ting Ho of almost 10 sec.-ft. per sq. mile for the effective drainage area, which may be compared with the 15 sec.-ft. stated for the Italian stream. Mr. Freeman's "possible" explanation for the relatively small run-off per square mile, would seem to apply with even greater force to the Yung Ting Ho where such a large part of the drainage basin is of loess formation, and where there is never any frost in the ground at the time of such storms. The total run-off from this basin for the months of July and August, 1924, was estimated at 53 300 000 000 cu. ft., while the precipitation was approximately 459 000 000 000 cu. ft. This is a run-off of about 11½% for the two months of the flood season.

While these comparisons show that the Po is the larger stream with greater unit run-off and maximum discharge, the discharge of silt by the Yung Ting Ho is much greater. This is perhaps more remarkable than any other feature of these floods of North China, and particularly so for this river. Samples have been taken which showed 10% of silt by weight for the Yung Ting Ho and as high as 11% for the Yellow River. These are of course maximum records, and it is quite probable that such high degrees of saturation are not usually of long duration. Hence, they would have relatively smaller effect on the total weight of silt transported annually; but amounts of from 2 to 5% by weight are not at all uncommon for much longer periods during the flood season. At the same time conditions often arise which tend toward high degrees of saturation locally; for example, when there is rapid erosion of high banks or loess cliffs, which cave off into swift currents so that the stream carries a very heavy load of silt for a short distance. The writer saw a whole village destroyed in three days in 1924 when the Pei Ho was in flood. Deep scouring undercut the banks so rapidly and the shifting of the channel was so inevitable, that the villagers were powerless to prevent the disaster. In fact, the channel has shifted about a mile from east to west within three years at this point.

Such conditions, where the river has built up the plain mostly of this loess formation, and where enormous quantities of similar material are transported annually, probably present the most important factors tending to cause the river to meander by distinct and widely separated channels in this region. The migrations of the Yellow River have been mapped and discussed at various times, and the Yung Ting Ho has had a very similar life history during almost 2 000 years of record.

The average annual volume of silt deposited by the Yung Ting Ho on its way from the mountains to the sea, has been estimated at 13 000 000 cu. yd., in

addition to which an unknown volume has been carried on and added to the yellow waters of the Gulf of Chihli to be spread finally on the bed of the sea or along the constantly extended shore. Approximately, this would be 14,000,000 metric tons of material used annually in building up the flood-plain and bed of this river. While the data on which this estimate is based are not conclusive, this subject has been given very careful study and the figures are believed to be conservative. This mass of silt is more than double that brought down by the Po with its larger basin, and yet, be it remembered, does not include that carried to sea. If this material were distributed uniformly over the entire effective drainage area of this river, it would amount to about 850 short tons per sq. mile, which is moved annually from the upper reaches of the river to the plains between the mountains and the sea. While the total amount is certainly much greater than that stated, it should also be remembered that the great bulk of this material comes from certain well-defined areas forming enormous deposits of loess. Much might perhaps be accomplished if this silt problem were attacked at its source, but as yet little or nothing has been done.

For a few miles below the mouth of the gorge where the river leaves the mountains, the bed is composed of very coarse gravel. Less than ten miles from the foot of the mountains the bed is composed almost entirely of sand. Farther down, this material becomes finer and finer, until there is nothing but silt in evidence on the more level plains. Unlike most rivers, the Yung Ting Ho does not now have any well-defined delta cone at the point where it leaves the mountains, due to the fact that it has been trained for centuries between well-maintained dikes, some having been built about 1350 A. D. Although this river now flows into the Pei Ho at a point 30 or 40 miles from the sea, it does have a "delta", so-called from the manner of its formation. This "delta" is from 6 to 20 ft. above the level of the surrounding plain. At its head are at least three distinct lines of dikes constructed to confine the river as it built up its flood-plain and bed, and this building is still going on, as it has for 200 years. Contrary to the opinion of the Italian authority, Frisi, the point where the building up of the bed is most rapid, is 40 or 50 miles below the last sign of gravel in the bed of the stream. Where the river has built up its bed well above the plain the sand and silt forming the river channel is extremely porous, causing enormous seepage losses. In June, 1924, a month before one of the highest floods of recent years, the river was dry at the head of the delta.

It is evident that with a reduction of 100% in the volume of flow, all silt must be deposited, and with a reduction of 50%, which is not uncommon, the amount deposited must be very large, with a decided tendency to maintain the degree of saturation, if it does not actually increase as one proceeds down stream. If the mouth of the Yung Ting Ho is taken at its junction with the Pei Ho on the east side of the delta, the change in elevation at this point in all probability has been little more than it would have been were it building out the coast line at its mouth for the same length of time. The size of this river, the volume and character of the silt transported, the topography and geological formation of its drainage basin, as well as the climatic conditions,

are all so different from those obtaining on the Po, that different results and conclusions would seem to be almost inevitable.

In addition to the dikes along the Yung Ting Ho, other devices have been used to assist in the control and regulation of floods. The simplest structure is an open spillway, or notch, in one of the dikes, with abutments and wing-walls which, as a rule, are built of excellent ashlar masonry laid with lime mortar. The crests and aprons are usually a mixture of earth and lime, which forms a sort of concrete. Under certain conditions, and with properly selected materials and good workmanship, this method of construction gives satisfactory results. In other instances abutments and wings as well as the aprons and crest, are of earth-lime concrete, and have stood for almost 200 years. A temporary dike is usually built on the crest of a spillway to a lower elevation than the main dike so that it will be over-topped or can be cut in case of an excessive flood.

Another spillway of cut-stone masonry, is in excellent condition after nearly 200 years of service. It was intended to be controlled by stop-logs, but the crest elevation is such that only the higher floods overflow it and at present (1928) no attempt is made at regulation.

Still another spillway was built for better control of floods on the Yung Ting Ho, as late as 1914, but this one shows foreign (probably French) influence in design and construction. It is located at the west end of the so-called Marco Polo Bridge near Peking, a most interesting and very ancient structure mentioned by that noted traveler. \*Between these last-mentioned weirs, the river dikes are very wide apart and form a channel reservoir having an area of more than 20 sq. miles, which has great effect in reducing flood peaks on account of the relatively large storage effect and also on account of the considerable absorption which takes place.

The earth dikes have piles of material distributed along the top for emergency repairs. This is common practice although the earth available is usually not sufficient for more than very minor repairs. The elevation of the channel reservoir above the surrounding country, together with the very porous nature of the deposits made by the river along its flood channel, doubtless accounts for the extraordinary seepage losses along this reach of the river. It is estimated that for a flood peak of 5 000 cu. m. above Lu Kou Chiao, about 1 100 cu. m. will be discharged over the weir at that place, while about 450 cu. m. more will flow over the cut-stone spillway. Between these points there is a probable further reduction in the crest discharge of about 700 cu. m. for the reasons stated.

All this may serve to emphasize the well-known facts that, while observation and experience with one stream are valuable in that the statement and analysis of the problems involved on that stream may be recorded for comparison, each river presents its own peculiar problems due to its own peculiar conditions. Only by the most careful study of the conditions and problems for each individual case, can one hope to arrive at anything approaching a satisfactory solution.

C. E. GRUNSKY,\* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—Current engineering literature is filled with accounts of works and structures recently completed and with discussions of pending problems. It is refreshing to get from time to time what Mr. Freeman has given the profession—an account of works which have functioned for centuries and which experience has shown to be adapted to the purpose for which they were constructed.

In the matter of flood control, the Engineering Profession has much to learn from this experience. There is only one point in connection therewith which, it seems to the writer, should be further stressed. The valley of the Po differs from the valleys of the Sacramento and the Mississippi mainly in the fact that the principal flood-control levees can be set far back from the stream in the upper parts of the valley. Broad areas of cultivable land protected against moderately high river stages by low submersible levees—summer dikes—flank both sides of the river. These have the same purpose, and function in the same way at extreme river stages as the by-pass areas in the Sacramento Valley. In the latter case, however, the areas set apart for occasional flooding could not, for topographical reasons, be located along the river; they had to be set back some distance from the high bank land. In both cases, however, the purpose is the same, that is, large cross-sectional area is provided in or along the river's upper reaches to hold water in temporary storage, thereby cutting down the maximum rate of discharge at points in the valley farther down stream.

JOHN R. FREEMAN,† PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The kindly words of Colonel Townsend about the information given in the paper are most welcome, especially his hearty appreciation of the work of the early Italian engineers. These men were the founders of hydraulic science, notwithstanding the fact that it required more than a century of their earnest work to place the square root sign in the formula for the discharge from an orifice, and that a hundred years still later it remained for a French engineer to invent the Chezy formula for stream flow.

During the Middle Ages, Northern Italy was the world's greatest center of universities, and those who governed the country called into service for river regulation and flood protection the foremost professors of physics and mathematics of their time. The writer believes that students in the new schools of hydraulic research at the great engineering colleges of Italy—with the aid of recently established hydraulic laboratories, and the new observations on the River Po—will learn more of controlling these waters economically in the next forty years than has been learned by work on the river alone in the past four hundred years.

Colonel Townsend refers to the fact that the Italian civil engineers are taught the fundamental principles of river hydraulics in the various engineering colleges of that country, while this subject is commonly ignored in American engineering colleges. The writer understands that almost every im-

\* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

† Cons. Hydr. Engr., Providence, R. I.

portant college in Europe has a Professorship in River and Harbor Hydraulics, while there is not yet one in any college on the American Continent.

The fundamental reason for this is that no attractive career opens, even to the brightest student from the foremost engineering college—whichever that might be—if he begins and continues as a United States Assistant Engineer. He can never rise to the top and have his name attached to any important structure (*vide* the experience of the late Alfred Noble, Past-President, Am. Soc. C. E.). Up to the present time the only door opening to such a career is by way of the National Military Academy at West Point. While the eminent Army engineer may retire at the age of 65, with a pension of about \$5 000 per annum, and thereafter carry on a lucrative consulting practice, even the ablest civilian engineer on river and harbor work in the United States must either resign, or work on at about one-half the salary of the West Point graduate until he is 70 years of age, when he will be dismissed, with a pension of only about \$1 000 per annum.

The Army method, which largely makes voucher clerks of the Resident Army Engineer's staff, and after a very few years on any one problem shifts the leading officers to new fields, cannot possibly produce the best results for research on river and harbor improvement; but it is doubtless the best peacetime method of training Army officers for a future war. Army methods assume that any one man can replace any other man of equal grade—and that is a necessity in the field of battle; but the fundamental facts of human nature remain—that probably not one good average engineer out of ten (perhaps only one out of a hundred), has the inborn talent to become a great research man and develop that initiative which advances the science and the art.

Colonel Townsend deprecates the need of hydraulic laboratories for studying river problems. If he should visit Italy and Germany again he would be amazed, as the writer was, to observe the development of that most useful of aids in experimental research, the Doctrine of Similitude, with the use of small, relatively inexpensive models, which is now placed in the hands of the skilled engineer striving to build better hydraulic turbines, and of those engaged in river and harbor engineering. It is the strongest tool ever invented for advancing the state of the hydraulic arts.

In due course it may revolutionize methods in research on river flow, and tidal action in harbors, just as the naval tank in the hands of Froude, fifty years ago, gave a new departure for problems in ship modeling.

So rapid and recent is this progress in the method of attack on hydraulic problems\* that many people have overlooked the remarkable research made in the hydraulic laboratory of the Engineering College at Manchester, England, on the projected creation of a great tidal water power by means of a dam across the estuary of the Severn River. It is interesting to note that a model of the river and bay, 40 miles long, is housed in a room 45 ft. square, and is constructed with such nicety and accuracy of detail that it cost about \$10 000.

\* "Hydraulic Laboratory Practice," pub. January 1, 1929, by the Am. Soc. Mech. Engrs., New York, N. Y.

The laboratory idea is developing and spreading so fast in Europe that, within the last year or two, great new hydraulic laboratories have been brought to completion by the Swiss Government at Zurich; by the Netherlands Government at Delft; the Norwegian Government at Trondhjem; and the Czechoslovakian Government at Prague. Surely such hydraulic laboratories are not built, as Colonel Townsend suggests, "for the purpose of rediscovering principles known in Italy for centuries and now taught in the ordinary textbooks of the engineering schools of Europe." It is the firm belief of the writer that tens of millions of dollars have been wasted on river and harbor work in the United States through failure to realize the value of the hydraulic laboratory and the applications of the doctrine of hydraulic similitude.

It is difficult for a stranger in a foreign land unfamiliar with the language to make sure that he correctly understands the data placed before him. Hence the writer values the discussion of Professor Giandotti particularly because of its acknowledgment that the "paper describes very well the actual conditions". Professor Giandotti emphasizes some of the finer points that the writer missed. Furthermore, the discussion is valuable because of the proof given in Fig. 14 that, although the elevations of the river bed fluctuate from year to year, as the volume of sediment is moved along, and that "while they are never the same from year to year, the elevations always oscillate about a line of equilibrium and show practically no appreciable net change."

The discussion by Professor Goodrich is of interest because of comparisons of conditions along the Po with those along certain waters in Chihli in Northern China. This confirms similar statements once made before the Society by the writer which at first were regarded as unbelievable. The percentage in volume of silt to water brought down by the River Po is surely very moderate as compared with that of some of these Chinese rivers.

Mr. Grunsky's contribution is of particular interest in further emphasizing the difference in the problems of flood control presented by rivers in various parts of the United States and of the world. Surely, however, the fundamental laws and principles of erosion, sedimentation, and stream flow, apply to all. The differences mentioned by Mr. Grunsky result simply from different values of the factors in the same general equation, presented by the variable circumstances of the drainage area and the precipitation in the several localities. The writer has been impressed with the differences in sediments, or materials, shoved along by the current, in rivers with rapid slope leading out from the Alps as compared with those found in the beds of most American rivers in the East. On the other hand, in rivers coming down the western slopes of the Sierras and the Cascade Mountains gravels and cobblestones are carried along as in the Alpine rivers. The mechanical laws are of universal application.

Regarding Colonel Slattery's dictum, that it is "unquestionably cheaper" to maintain the necessary depth by dredging than by spur-dikes and retards, the writer suggests that dredging was long ago developed to the maximum possibilities of efficiency, while spur-dikes and retards of twenty years ago

may have fallen very far short of the best and most economical that could be devised by further studies in the laboratory and in the field. The time has come to re-open some of the questions that were considered "settled" forty years ago.

Colonel Slattery well describes the marvelous efficiency with which levees were topped out by sand-bags during the Mississippi flood of 1916. The writer, as a student of river hydraulics, followed the greater flood of 1922 along down the river, and was thrilled by the wonderful rapidity and efficiency with which levees were pieced up, sand-bags placed, and threatened crevasses checked; and he fully believes that no better or more energetic work has been accomplished anywhere in the world, in times of such great emergency. Much of it was done by civilian engineers and chiefs of levee districts. Nevertheless, the work along the Po in the great flood of 1927, by which 30 miles of sand-bag dikes were placed on top of the dikes of the river, which rises much more rapidly than the Mississippi, is of a similar order of excellence and probably superior in some of the details. The sudden rise of the Po permits no such relatively leisurely preparation in collecting grain sacks, from a thousand miles away as is possible along the Lower Mississippi, where the flood height following abnormal rains can be predicted with a fair degree of precision several weeks in advance.

Regarding the fact, that "overflows [along the Mississippi] are not always an unmitigated curse", the writer believes that something can be learned from the system along the River Po, where there are two sets of dikes, one near the river and a higher one farther back, with numerous cross-sections, thus permitting an occasional overflow and enrichment of the broad strip near the river. So far as the writer could learn, the valley floor of land subject to inundation along the Po does not pitch back from the river, or decline in altitude, to any such degree as that along the Mississippi, where, in general, the bottomlands near the river are fully 5 ft. higher than they are a mile back. This condition along the Mississippi is adverse to arranging a system of double dikes as along the Po; but the writer is strongly inclined to believe that thorough study would show that a double dike system in certain parts of the Mississippi delta would give the best possible protection, and by proper design of intakes would permit periodically flooding the intermediate land for restoration of fertility. In contrast to the Po, the dike nearest the Mississippi should be the main line of defense, and the series of secondary dikes, running in straight lines about  $\frac{1}{2}$  mile back from the apex of principal bends, should here be regarded as the second line of defense, which would prevent the flood from escaping and flooding, for example, the whole Yazoo Valley from an unsuspected sand-boil and midnight crevasses.

Replying to the questions of Mr. Davis, the writer found that there was apparently no doubt among Italian engineers that the Po was steadily lengthening its delta, and projecting its load of sediment into the Adriatic, thereby constantly lengthening the river's course.

Dr. de Thierry, who was born in Northern Italy, knows the history, the language, and the work of the Italian engineers. Perhaps his most useful contribution to this discussion is that about the time factor involved in the study and working out of these great river problems, which he suggests is a matter of a century or so; and, that "the Po, like every other river, is, in effect, a living organism, the study of which requires more than the lifetime of any one man."

Paper No. 1727

### ONE HUNDRED FIFTY YEARS ADVANCE IN STRUCTURAL ANALYSIS\*

By H. M. WESTERGAARD,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. S. TIMOSHENKO, ALFRED D. FLINN, JACOB FELD,  
AND H. M. WESTERGAARD.

#### SYNOPSIS

The story of the advance of structural analysis is, in the main, an account of the work done by individual men. While the science of structural analysis is international, at the same time its national traditions are significant. In the French tradition the names of Coulomb, Navier, and Saint-Venant stand out; in the English tradition the name of Rankine; in the German, the names of Mohr, Müller-Breslau, and Föppl; and there is a Russian tradition which may be traced back to the influence of Euler.

The account which follows begins, somewhat arbitrarily, but (as will be seen) not entirely without justification, with the work of Coulomb. Consideration is given, however, to his predecessors. An attempt is made to sketch the development from this early period to the present.

The ancient bridges, the vaults, arches, and flying buttresses of the great medieval cathedrals, and the riggings of sailing vessels at the height of their development, bear witness of structural insight on the part of the builders; but the art of structural analysis, except for small beginnings, is only about 150 years old.

Structural analysis is based on the physical properties of materials; its method is mathematical; its purpose is design. It came into existence by a meeting of physics, mathematics, and engineering.

## COULOMB, 1776

In 1776, the Paris Academy of Sciences published a paper by Charles Augustin Coulomb, entitled, "Essai sur une application des règles de Maximis et Minimis à quelques Problèmes de Statique, relatifs à l'Architecture".\* Coulomb, who lived from 1736 to 1806, was a military engineer. He possessed mathematical insight and attained distinction as a physicist in the fields of mechanics, electricity, and magnetism. Discussing beams with rectangular cross-section, in the paper of 1776, he assumed the fibers to offer resistance proportional to their extension or shortening; he considered the balancing of the internal forces acting upon a cross-section; and he determined, by accurate reasoning, the position of the neutral axis and the moment of the internal forces. He remarked that at rupture, in some cases, the neutral axis may be at a different position. In the same paper, he considered the deformation by shear in connection with the failure of a solid; and he presented his theory of earth pressure on a retaining wall, according to which a wedge of earth slides when the friction and cohesion in a plane section become insufficient.

Saint-Venant remarked eighty years later† that in this paper "one finds presented almost all the bases of the theory of stability of structures." If one considers the combined circumstances of Coulomb's capacity for exact science and his early relation to practical affairs of engineering, it is not strange that he should be the author of so significant a document.

It is perhaps stretching a point to state that, because of this paper, Coulomb is the "Father" of structural analysis. He certainly is one of the "Fathers".

## COULOMB'S PREDECESSORS

It would be unreasonable, however, not to consider Coulomb's predecessors.‡ Galileo, in a dialogue published in 1638, inquired into the problem of the strength of a cantilever. He considered the beam to be perfectly rigid except for the turning about a horizontal axis in the section of rupture. In spite of certain incorrect assumptions he obtained a correct design of a cantilever of uniform strength for the case of a rectangular cross-section. Hooke, in 1678, announced his famous law that deformations are proportional to the loads. Mariotte at about the same time arrived at the same law, and applied it to the fibers of a beam. Tests (made by him in 1680) led him to the observation that some of the fibers of a beam are stretched and others shortened. He placed arbitrarily the boundary between extension and shortening at the middle of the beam. Varignon, to whom credit belongs for early developments in statics§ (for example, the polygon of equilibrium of a string), discussed the investigations of Galileo and Mariotte.¶ Varignon computed a moment

\* In the volume for 1773 of "Mémoires de Mathématique et de Physique, Présentés à l'Académie Royale des Sciences, par divers Savans, et lus dans ses Assemblées," pp. 343-382.

‡ A very complete account of the development of ideas and methods relating to the theory of elasticity and strength of materials may be found in the great work of Todhunter and Pearson, "A History of the Theory of Elasticity and of the Strength of Materials," Cambridge Univ. Press, 1886-95. A shorter account is given by A. E. H. Love in the historical introduction to his "Mathematical Theory of Elasticity," Third Edition, 1926. See, also, H. Lorenz, "Technische Elastizitätslehre," 1913, pp. 644-683.

§ P. Varignon, "Nouvelle mécanique ou statique," 2 vol., Paris, 1725.

¶ In a paper published in the *Mémoires* of the Paris Academy, in 1702.

of resistance of a cantilever by assuming the tensile force of the fibers to be proportional to the distance from an axis, but, unfortunately, in spite of Mariotte's observation of shortened fibers, he placed this axis at the bottom of the cross-section.

James Bernoulli, the earliest member of the distinguished Bernoulli family to attain fame as a mathematician, at the end of the Seventeenth and the beginning of the Eighteenth Centuries introduced the problem of determining the shape of the elastic curve. After him is named the assumption that a plane cross-section of a beam remains plane after bending. He arrived at the peculiar, inadmissible conclusion that the position of the neutral axis is indifferent. His nephew, Daniel Bernoulli, about 1735, obtained a differential equation for transverse vibrations of a bar.

Leonhard Euler was born in 1707 in Basel, Switzerland, the city of the Bernoullis. In 1727 he was called to the St. Petersburg Academy by Catherine I, and in 1741 to the Berlin Academy by Frederick the Great. He returned to St. Petersburg in 1766 by invitation of Catherine II, and died in 1783. He was endowed with a magnificent intuition, and was one of the great mathematicians of all times. The Bernoullis influenced him to attack the question of the elastic curve. In order to understand his method, it should be noted that the science of physics in the Eighteenth Century was still struggling to emancipate itself from metaphysics. In a manner characteristic of this state of development, he argued\* from the premise of the perfection of the universe to a principle of least action. In this way he established a principle of minimum for the flexure of beams, and he gave solutions for a number of cases. In a later paper, of 1757, entitled "Sur la force de colonnes",† he derived the celebrated formula which is named after him, and which expresses the critical load at which a slender column buckles.

In this early work on the elastic curve of beams and columns the quantity which is now represented by the product of the modulus of elasticity and the moment of inertia was given as a single "moment of stiffness", characteristic of the beam or column. Euler suggested determining experimentally this moment of stiffness ("moment du ressort" or "moment de roideur") by supporting the beam or column as a cantilever and measuring the deflection at the end, due to a transverse force at that point, a case in which the deflection could be obtained by a simple formula.

In addition to his work on the static elastic curves, Euler, during his later years, investigated successfully the transverse vibrations of beams, and, by an attempt to analyze the vibrations of bells, he began the work on the two-dimensional problems of plates and shells.

#### PROGRESS AND RELAPSES, 1776-1820

Consider again the paper by Coulomb, published in 1776. In spite of the unquestioned importance of the work of his predecessors, especially that of the great mathematician, Euler, Coulomb's paper stands out as a most important original document produced by an engineer, that deals with struc-

\* Euler, "Methodus inveniendi lineas curvas maximi minimive proprietate gaudentes," Lausanne, 1744, Additamentum I: "De curvis elasticis."

† Published in the *Mémoires de l'Académie de Berlin*, v. 13, 1759.

tural analysis for the sake of the structure. This paper does contain, in addition to other important material, the first adequate analysis of the fiber stresses in a beam.

It must not be thought, however, that Coulomb's analysis of the beam at once settled this issue in the minds of all others who were concerned with it. Girard published, in 1798, a treatise on the resistance of solids.\* A German translation was published in 1803. This book is the first treatise on mechanics of materials. It has a historical introduction, and contains extensive accounts of the earlier works from Galileo to Euler and Lagrange. It reports tests performed on wooden beams by the author, and it is significant on account of the importance attached to experiments. Tests are in, and metaphysics is out. Girard, however, accepted James Bernoulli's incorrect conclusion that the position of the neutral axis is indifferent.

The learned Dr. Thomas Young, famous as a physicist and a philologist, made two lasting contributions to the subject of elasticity.† One is the discovery of the detrusion, or shearing deformation, as an elastic deformation (Coulomb had considered it as a permanent set in connection with failure); the other is the introduction of the modulus of elasticity, which is often named after him. Young, still, was uncertain and obscure as to the position of the neutral axis.

The textbooks from the beginning of the Nineteenth Century, in dealing with the subject of the strength of beams, are not very satisfactory. Olinthus Gregory, in his "Treatise of Mechanics, Theoretical, Practical, and Descriptive", London, 1806 (and in the later edition, 1815), accepted Galileo's results, because they are simple, and ignored the others. Todhunter and Pearson‡ refer to this book as evidence of "the depth to which English mechanical knowledge had sunk at the commencement of the nineteenth century." The book by John Banks, "On the Power of Machines" (1803), contains practical rules and erratic theory for the design of beams. Eytelwein,§ who possessed better mathematical understanding than his two contemporaries just mentioned, introduced the subject of beams well, but fell into the old error of placing the neutral axis in the concave surface of the beam.

In France, Duleau in his "Essai théorique et expérimental sur la résistance du fer forgé" (Paris, 1820), quoted Coulomb on the subject of the neutral axis, but misunderstood him. In England, Tredgold in his two standard textbooks, "The Elementary Principles of Carpentry" (London, 1820), and "A Practical Essay on the Strength of Cast Iron" (London, 1822), displayed confusion in matters of theory. Hodgkinson, an able experimenter, contributed toward correcting the current errors about the neutral axis, especially through two papers published in 1824 and 1831 by the Manchester Literary and Philosophical Society. Barlow was erratic on the subject. In the edition of 1837 of his "Treatise on the Strength of Timber and Cast Iron,

\* P. S. Girard, "Traité analytique de la résistance des solides, et des solides d'égalé résistance, auquel on a joint une suite de nouvelles expériences sur la force, et l'élasticité spécifique des bois de chêne et de sapin," Paris, 1798.

Malleable Iron and Other Materials" (page 63), he finally adopted Coulomb's principle for determining the neutral axis. He credited this principle to Hodgkinson.

#### THE FOUNDING OF THE THEORY OF ELASTICITY, 1820-1830

The picture of advance in structural analysis again becomes cheerful when one turns the attention toward France during the decade from 1820 to 1830. Three names stand out: Navier (1785-1836), Cauchy (1789-1857), and Poisson (1781-1840). These three men are considered to be the founders of the theory of elasticity. Navier, who became Professor of Mathematical Analysis and Mechanics at the École Polytechnique in Paris, combined ability in mathematics with competence in practical affairs of engineering. Cauchy entered the École Polytechnique in 1805 and the École des Ponts et Chaussées in 1807, and began a career as an engineer. In 1813, however, the two great mathematicians, Lagrange and Laplace, influenced him to renounce engineering for mathematics. Poisson, like Navier, was a Professor at the École Polytechnique. He was an ingenious and successful mathematician. His interests were directed toward pure science rather than toward its applications.

It was in 1821 that Navier submitted to the Paris Academy the investigation by which he originated the theory of elasticity of three-dimensional solids. By considering forces acting between the molecules according to a definite law of attraction and repulsion he established, for the first time, a set of equations for the equilibrium and the vibrations of the interior parts of a solid. At about the same time interest in the questions of waves of light aroused Cauchy to a study of the mechanics of an elastic medium. He succeeded, before the end of 1822, in setting up the fundamental relations of elasticity (in the form now current), in terms of the principal directions of stresses and strains, the six components of stresses and strains, respectively, and in terms of differential equations for the three components of displacement. Cauchy, later, added studies of the elasticity of crystals, which, on account of different properties in different directions, may have as many as twenty-one independent elastic constants (that is, constants of the nature of Young's modulus or Poisson's ratio). Poisson's most important contribution was presented to the Paris Academy in 1828\*. This paper, besides fundamental theory, contains numerous specific applications.

It should be remarked that the theory of elasticity is primarily physics, aimed at the understanding of matter. The development of the fundamental processes of theory, through the past one hundred years, has been the joint work of physicists, mathematicians, and engineers. Applications to the molecular theory and the theory of sound have presented themselves. At the same time, applications to structural analysis have been a cause of continual contact with engineering. These practical applications to engineering have come into the foreground during more recent years.

\* Published in the *Mémoires*, v. 8, 1829, pp. 357-570.

## MECHANICS OF ENGINEERING ACCORDING TO NAVIER

Navier, scientist, engineer, and professor, became the author of the first great textbook on mechanics of engineering. The first edition of his "Résumé des leçons données à l'École des Ponts et Chaussées sur l'application de la Mécanique à l'établissement des constructions et des machines", was published in 1826, and the second, revised edition in 1833. The book appeared also in an Italian translation. It is evidence of the great influence of this book, and of the high esteem in which it was held, that Barré de Saint-Venant, one of the great classics in the theory of elasticity, undertook, a number of years after the death of Navier, the preparation of a third, annotated edition, which appeared in final form in 1864.\*

Navier, in the preface to the first edition, expressed well the purpose of structural analysis by comparing the stagnancy resulting from design by imitation with the progress which scientific methods make possible. The book, eminently practical, draws extensively on the experimental material available at the time. Of importance is the treatment, new because of its completeness, of the subject of beams. Stresses are determined for any cross-section, and the deflections are found by the method of double integration. This treatment is based on Bernoulli's assumption, often named "Navier's hypothesis," that the plane cross-section remains plane after bending. It was an accomplishment of investigators in the theory of elasticity of a later day, especially Saint-Venant and Pearson, to show that the errors introduced by this approximate assumption are only small for beams of ordinary dimensions. The result is that Navier's treatment of beams has become justly traditional. Although some additions have been made to it, this treatment holds its place in structural analysis in engineering of the present day.

Navier dealt competently in his "Mécanique" with subjects such as earth pressures, stability of masonry arches, and timber structures.

He treated particular cases of continuous beams, and he gave an analysis of the deflections of curved beams with a not too sharp curvature. He applied the latter analysis to some cases of two-hinged elastic arches. In 1825, Navier had published a note on the statics of bodies supported at more than three points.† He made therein the observation that a statically indeterminate problem becomes statically determinate if one takes into account conditions of elasticity. Except for some cases of statically indeterminate beams, which had been analyzed before, this note, in connection with the several cases treated in the book, represents, as far as is known, the beginning of the analysis of elastic, statically indeterminate structures. The same problems can be solved more easily by modern methods, but Navier's solutions are legitimate.

Navier applied the assumption of the plane cross-section remaining plane to torsion. This is proper in the case of a circular section, but improper in the case of non-circular sections. It was Saint-Venant who accomplished the

\* This third edition, besides the additions to the text, contains an account of the life of Navier and a general historical introduction.

† Navier, "Sur des questions de statique dans lesquelles on considère un corps supporté par un nombre de points d'appui surpassant trois," *Bulletin des Sciences à la Société Philomatique*, 1825, p. 35.

difficult task of producing an exact theory of torsion for non-circular sections, and he inserted this theory in the third edition of the "Mécanique".

Navier's book is written with admirable clarity. It is no wonder that it exerted a great influence.

Two more of the works of Navier should be mentioned. In 1820, he submitted to the Paris Academy a paper on the flexure of slabs. Lagrange had obtained in 1811 a differential equation for this type of flexure. Navier gave an accurate solution for the case of a rectangular slab simply supported on four sides. The other work to be mentioned is a report of 1823 on his examination of English suspension bridges. It is significant that he tried to solve problems of the vibrations of the bridge.

#### THE FRENCH TRADITION

Lamé (1795-1870) and Clapeyron (1799-1864) were French engineers, who were for a time in Russian service. They contributed some papers jointly, especially one on the theory of internal equilibrium of solids, which was published by the Paris Academy.\* This paper contains a number of definite applications of the theory of elasticity. Lamé published, in 1852, a volume of lectures on the theory of elasticity.† His formulas for the stresses in thick cylinders with internal pressure are well known. Clapeyron established an important formula, named after him, for the internal energy of an elastic body, due to the stresses.

In a short paper published in 1857‡ Clapeyron presented the famous "theorem of three moments" by which continuous beams may be analyzed conveniently. The paper has the appearance of a preliminary announcement of a longer paper, which, however, was never published. The form is rather interesting. The author begins by referring to the immense capital invested in railroads and the resulting growth of the problems of the engineers. He mentions a particular bridge with continuous girders, and says that practice here, as so often, has preceded theory. He states the formula, and shows by an example how to apply it.§

The great classic in the theory of elasticity, Barré de Saint-Venant (1797-1886), has been mentioned already in connection with the third edition of Navier's "Mécanique." Saint-Venant was an engineer and a mathematician. Most famous is his work on the subject of torsion.|| Saint-Venant gave exact solutions for a number of definite cross-sections. Knowing the needs of engineers, he did not satisfy himself with establishing procedures of computation, or solutions in terms of infinite series, but he computed numerical coefficients, and represented many of the results graphically in a manner readily intelligible to any trained engineer.

\* Mémoires présentés par divers Savants, 1833.

‡ Comptes Rendus, Paris Academy, v. 45, p. 1076.

§ The theorem of three moments is frequently named after Clapeyron, through whom it became generally known. It was given earlier, however, by Bertot, in *Comptes Rendus de la Société des Ingénieurs Civils*, 1855, p. 278. A more general form, applicable not only to a uniform load on each span, but to any type of load, was given later by Bresse.

|| "Mémoire sur la torsion des prismes, etc." pub. by the Paris Academy in "Mémoires des Savants Etrangers," 1855, pp. 233-560.

One may explain the existence of a French tradition in structural analysis by referring to Navier and Saint-Venant. This tradition was upheld by disciples of Saint-Venant, among whom should be mentioned Boussinesq, H. Resal, Lévy, and Flamant. The researches of Boussinesq in a variety of fields of the theory of elasticity, theoretical and applied, as well as in the theory of earth pressures, are of considerable depth. H. Resal originated in 1862 an acceptable approximate theory of sharply curved beams (or hooks)\*. Lévy wrote an extensive and valuable treatise, "Statique graphique" (Paris, 1874, Second Edition, 4 vol., 1886-88). And Flamant wrote treatises on structural statics and strength of materials.†

It was in France in 1894 that E. Coignet and N. de Tédesco, in a report to the Société des Ingénieurs Civils, originated the method which is now commonly used for computing nominal stresses in reinforced concrete beams for the purpose of design. This computation is based on neglect of horizontal tensile stresses in the concrete, on a linear relation otherwise of stresses and strains, and on the assumption that the plane cross-section remains plane.

A. Mesnager is a prominent contemporary representative of the French tradition. He introduced and made practicable the analysis of a complex structure by applying polarized light to a transparent model.‡ He has made important contributions to the theory of flexure of slabs.§

#### ENGLAND

France had Navier; Great Britain produced W. J. M. Rankine (1820-72). As Professor of Civil Engineering and Mechanics in the University of Glasgow, Rankine wrote remarkable textbooks in various fields of engineering. The first edition of his "Manual of Applied Mechanics" was published in London in 1858, the nineteenth edition in 1914. This book stands side by side with Navier's "Mécanique" as a great textbook on mechanics of engineering. New in this book is the determination of the distribution of shearing stresses in a beam by the analysis now current.|| Another mark of progress is the introduction of the formula, which has been named after Rankine, for the strength of columns. Although not perfect, this formula has been of great service. Rankine credits the formula to Gordon. It had been proposed previously by F. Schwarz in 1854.

Rankine treated the problem of earth pressures from the point of view of a plane state of stress. His solution compares in importance with that of Coulomb. The two theories agree in important cases.

Rankine wrote numerous scientific papers, some of which deal with the theory of elasticity.

To understand the English tradition one must refer to Rankine; to his predecessors, Hodgkinson on the practical, experimental side, and the great mathematicians, Green and Stokes, on the side of the mathematical theory

of elasticity; also to two great physicists of the Nineteenth Century, Maxwell and Lord Kelvin; and to Todhunter and Pearson, authors of the monumental "History of the Theory of Elasticity" (Cambridge, 1886-93). The practical problems of structural mechanics have been represented during recent years, for example, by A. Morley, author of noteworthy treatises on "Strength of Materials" and "Theory of Structures"; and the mathematical theory of elasticity has an eminent contemporary representative in A. E. H. Love, author of a great treatise on this subject (first edition, 1892-93; third edition, 1920).

#### EARLY WORKS ON TRUSSES

The prominent American engineer, the late Squire Whipple, Hon. M. Am. Soc. C. E., inventor of the Whipple truss, published a work on "Bridge Building"\* in 1847. This work contains an analysis, which, so far as is known, is the first legitimate analysis of the jointed truss. His style reveals a clear mind. He accomplished his task by means of the simplest possible principle of statics, that of the force resolved into a vertical and horizontal component. The American engineer, Herman Haupt, evidently independent of Whipple, followed in 1851 with an attempt to analyze trusses.† One finds in his work rather a mixture of sound and unsound thinking.

In 1863, August Ritter, in Germany, published his famous method of sections by which each stress is found by expressing the moments of all forces on one side of the section with respect to a suitable center.‡ This method holds its place at the present day as a most effective way of determining stresses in trusses.

#### GRAPHICAL METHODS

Graphical methods have played an important part in structural analysis. A "graphical statics" exists.

Particular graphical methods were used fairly early. Poncelet, for example, proposed, in 1840, his elegant method (frequently credited to G. Rehbann in 1871) for determining the earth pressures which exist according to Coulomb's theory. The English clergyman and Professor of Natural Philosophy, H. Moseley, a disciple of Poncelet, introduced in 1833 the line of pressure of the masonry arch.§

C. Culmann, born in 1821, was a Professor at the Polytechnikum in Zürich, Switzerland, from 1854 until his death in 1881. While Varignon in his "Nouvelle mécanique" of 1725 had studied the polygon of equilibrium of a string, it is reasonable to state that graphical statics as an independent

\* See S. Whipple, "Elementary and Practical Treatise on Bridge Building," an enlarged and improved edition of the author's original work; Second Edition, N. Y., 1873. Reference is made in the preface to the "Original Essays" of 1847. See, also, H. G. Tyrrell, "History of Bridge Engineering" (published by the author, Chic., 1911), p. 166; or the historical section in a very excellent book by J. I. Parcel and G. A. § H. Moseley, "On the Equilibrium of the Arch" (paper read 1833), *Transactions, Cambridge Philosophical Soc.*, v. 5, 1835, p. 293; or "The Mechanical Principles of Engineering and Architecture," Lond., 1843, p. 403.

subject came into existence when Culmann, by emancipating himself from the idea of a material string, made the string polygon a tool of analysis. Culmann found many uses for the string polygon; for example, in the analysis of masonry arches; and in determining the moment of inertia of an area. In the analysis of trusses he introduced a method of sections similar to that of Ritter, except that the three stresses in the section are found graphically as components of the resultant of the external forces on one side of the section. Culmann's remarkable book on structural mechanics, published in 1864-66, has the title, "Graphische Statik".

J. Clerk Maxwell (1831-79), the great English physicist, invented, in 1864,\* the stress diagram for trusses which unites into a single figure all the individual force polygons. Cremona developed the method further. The diagram is often named after Maxwell and Cremona. It found its place quickly in graphical statics of engineering.

Graphical statics owes a great deal to Otto Mohr (1835-1918), for a number of years Professor at the Technische Hochschule in Dresden, Germany. In 1868 he published his method of finding deflections of a beam by use of string polygons. He established on the same occasion the closely allied method of computing deflections as if they were bending moments.† The late C. E. Greene, M. Am. Soc. C. E., at the University of Michigan, about 1873, discovered a related principle of moments of areas by which one may find the deflection of any point of a beam, measured from a tangent to the elastic curve. H. Müller-Breslau, in 1885, gave Mohr's principle a general formulation,‡ with the application extended to trusses; the general principle includes Greene's principle as a special case.

Mohr invented a use of string polygons in determining stresses due to bending combined with compression when the material has no tensile resistance. C. Guidi, in Italy, showed in 1906 that this method, with a small modification, can be applied to a reinforced concrete member with any symmetrical cross-section.

Mohr devised an elegant graphical representation of the three-dimensional state of stress at a point, and he invented the circle of inertia for determining moments of inertia of an area with respect to different axes through the same point. Land showed later§ that the latter diagram may be applied advantageously in analyzing a plane state of stress at a point.

E. Winkler introduced the influence line in 1867.

Williot proposed, in 1877, his diagram by which the displacements of all points of a truss are obtained as vectors.||

After Culmann's death, W. Ritter continued his work at the Polytechnikum in Zürich. Ritter's treatise¶ possesses distinction and originality. The

ellipse of elasticity, proposed and used extensively by W. Ritter, has interested many. No one will deny its value in defining qualitatively the nature of the stiffness of a flexible connection between two elements of a structure.

Some graphical methods refer to continuous beams. Two should be mentioned, one originated by Mohr, the other by Claxton Fidler. Mohr's method is based on properties of the tangents to the elastic curve. Culmann, Winkler, and especially W. Ritter\* took up the idea and extended its use. The other method, which has turned out to be simpler, may be interpreted as a graphical solution of the equation of three moments. Claxton Fidler originated it in 1883, Müller-Breslau gave it in an improved form in his "Graphische Statik der Baukonstruktionen", and Ostenfeld developed it further.† L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E., have presented the same method.‡

#### STATICALLY INDETERMINATE STRUCTURES

The theories of statically indeterminate structures may be grouped according to certain leading principles, essentially four.

Maxwell, the great English physicist, originated the first of these in 1864,§ the same year that he invented the stress diagram for trusses. It was on this occasion that he gave the famous theorem of reciprocal deflections which is named after him. In dealing with the statically indeterminate truss he expressed the condition of geometrical coherence by a set of equations in which the redundant stresses are the variables. Mohr, in 1874, derived the same equations by a direct use of the principle of virtual work. The equations are named frequently after Maxwell and Mohr. Mohr's papers on the subject|| established firmly the applicability of the principle. He included the effects of variations of temperature. Müller-Breslau, in his weighty treatises,¶ included the effects of settlements of the supports and of incorrect initial dimensions of the members, and he extended the method so as to make it apply to solid frames as well as to trusses.

\* See v. 3 (published 1900) of his "Graphische Statik," previously mentioned. This volume has the sub-title, "Der kontinuierliche Balken."

† T. Claxton Fidler, *Minutes of Proceedings*, Inst. C. E., v. 74, 1883, p. 196. See, also, his "Practical Treatise on Bridge Construction," Lond., 1887, Fifth Edition, 1924, Chapter 9. H. Müller-Breslau gave the method in a more general form in an article, "Ueber einige Aufgaben der Statik, welche auf Gleichungen der Clapeyronschen Art führen," *Zeitschrift für Bauwesen*, v. 41, 1891, Columns 103-128, and thereafter in his "Graphische Statik der Baukonstruktionen," v. 2, sub-vol. 1, Leipzig, 1892, p. 357 (Fifth Edition, 1922, p. 406); also, v. 2, sub-vol. 2, 1908, p. 37 (Second Edition, 1925, p. 93). A Ostenfeld's treatment of the subject may be found in his "Teknisk Elasticitetslære," Second Edition, Copenhagen, 1905, p. 176; Fourth Edition, 1924, p. 230; in his "Teknisk Statik," v. 2, Copenhagen, 1903, p. 92; Third Edition, 1925, p. 87; and in two papers, "Graphische Behandlung der kontinuierlichen Träger mit festen, elastisch senkbaren oder drehbaren, und elastisch senk- und drehbaren Stützen," *Zeitschrift für Architektur und Ingenieurwesen*, v. 51, 1905, Columns 47-66, and "Graphische Behandlung der kontinuierlichen Träger mit elastisch senkbaren Stützen," *loc. cit.*, v. 54, 1908, Columns 57-78.

H. Müller-Breslau (1851-1925), for many years a Professor at the Technische Hochschule, in Berlin, is indeed one of the most distinguished figures in the history of structural statics.\* In addition to the many other contributions, he is responsible for the systematizing of what may be called the second leading principle in the analysis of statically indeterminate structures.† The procedure may be looked upon as a variation of that of Maxwell. The essential variables, again, are the redundant stresses (or measures of combined states of stresses, such as bending moments). The linear equations expressing the condition of geometrical coherence are obtained by superposition of displacements due to the individual loads. The coefficients in these equations are displacements due to unit loads. By expressing the individual terms by the principle of virtual work, the equations assume the form obtained by Maxwell and Mohr. The general form, however, in which Müller-Breslau stated these equations leaves the way open to obtain the terms by any method which is available for determining displacements. Müller-Breslau pointed out the usefulness, in this connection, of Maxwell's theorem of reciprocal deflections, and thus he came to the important conclusion that the influence line for a redundant stress or bending moment may be interpreted as a diagram of deflections. During recent years George E. Beggs, M. Am. Soc. C. E., at Princeton University, using this property of the influence line, has developed an experimental method which appears promising in connection with frames which are many times statically indeterminate; he obtains influence lines by observing deflections of models made of paper or celluloid.‡

The third of the leading principles is that of least work. This principle was established brilliantly during the Seventies by the Italian engineer A. Castigliano (1847-84). It should be mentioned that the Italian Count who later became a General, L. F. Menabrea, had stated the principle in 1858.§ The method, however, is named fairly after Castigliano rather than after Menabrea, whose proof was erratic. Castigliano presented his method in a remarkable book, "Théorie de l'équilibre des systèmes élastiques et ses applications" (Torino, 1879). The unknown quantities determined first are the same as those entering in the equations due to Maxwell and Mohr. Müller-Breslau contributed greatly toward making Castigliano's work known; and E. S. Andrews, in England, performed a service by translating Castigliano's book into English, under the title "Elastic Stresses in Structures" (London, 1919).

The fourth and last of the leading principles has been used on a number of occasions, but was given a general formulation only recently by A. Ostfeld, in Denmark. By this principle the unknown quantities upon which the analysis depends primarily, are deformations. The equations of elasticity are of the same form as Maxwell's and Mohr's equations, except that loads and deformations have changed places. Ostfeld published a book on this sub-

\* A list of Müller-Breslau's publications may be found in *Zeitschrift für angewandte Mathematik und Mechanik*, v. 5, 1925, p. 277.

† "Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen," 1886.

§ *Comptes Rendus*, Paris Academy, v. 46, 1858, p. 1056.

ject in 1925, entitled "Die Deformationsmethode". Such methods as the slope-deflection method, by which slopes and transverse deflections are the essential unknowns, may be interpreted as examples of application of this general principle.

Among the great textbooks dealing with statically indeterminate structures, with the greatness measured by quality and influence, should be mentioned the following: Müller-Breslau's "Graphische Statik der Baukonstruktionen"; Ostenfeld's "Teknisk Statik" (the last edition of which includes the deformation method, see v. 2, Third Edition, Copenhagen, 1925); and the book by the late J. B. Johnson, the late C. W. Bryan, and F. E. Turneaure, Members, Am. Soc. C. E., entitled "Modern Framed Structures" (Ninth Edition, v. 2, New York, 1911).

Germany, with leaders like Mohr and Müller-Breslau, played an important part in the development of this subject.

#### THEORY OF ELASTICITY

The theory of elasticity has been applied to practical problems in many ways during recent years. A. Föppl (1854-1924), not least through his wonderful book, "Technische Mechanik", the fifth volume of which deals with the theory of elasticity (v. 5, First Edition, Leipzig, 1907), doubtless exerted a great deal of influence in this respect.\* In 1920, he and his son, L. Föppl, who later became his successor as Professor at the Technische Hochschule, in Munich, published jointly a two-volume theory of elasticity for engineers, with the peculiar title "Drang und Zwang".

W. Ritz in a notable paper published in 1908† gave emphasis to a principle of minimum which lends itself particularly well to approximate solutions. Admissibility of approximate methods extends the field of accessible problems greatly. Ritz's principle of minimum is based on variation of shape, whereas Castigliano's principle is based on variation of the state of stress. Approximate investigations based on the minimum of energy by variation of shape are described frequently as analysis by Ritz's method.

A. and L. Föppl's "Drang und Zwang" contains many examples of this type of analysis.

Important work has been carried out during recent years on torsion, especially by L. Prandtl and A. Föppl.‡ Prandtl discovered in 1903 the "soap-film analogy", by which problems of torsion may be solved. He showed that the equations governing the state of stress in torsion are the same as those governing certain properties of a soap film deflected by a pressure from one side. Thus, one may transfer solutions by analogy from one field of mechanics to another. The soap film, being easy to visualize and to produce experimentally, and being subject to fairly simple laws of mechanics, has proved to be very useful in this respect.

Much work has been done during the last ten or fifteen years on the subject of the flexure of slabs. Two names should be mentioned: A. Nádaï in

\* A list of A. Föppl's technical and scientific publications, including eighty-five items, may be found in *Zeitschrift für angewandte Mathematik und Mechanik*, v. 4, 1924, p. 530.

† *Crelles Journal*, v. 135, 1908.

‡ See A. and L. Föppl, "Drang und Zwang," v. 2, 1920.

Germany and B. Galerkin in Russia. Nádai wrote an excellent book, "Die elastischen Platten" (Berlin, 1925), in which many of the recent investigations are described.

H. Reissner, in Berlin, and E. Meissner, in Zürich, have made important contributions to the theory of domes and shells.\*

#### RECENT DEVELOPMENTS

The plastic stage, occurring when certain stresses exceed the proportional limit or the yield point, has been the object of some theoretical studies during the more recent years.

The action of a column of ductile material presents a problem of this kind. If one wishes to understand this action, it is necessary to consider the changed conditions of stiffness beyond the proportional limit. Engesser and Considère discussed the mechanics of this case some time ago. A fully satisfactory treatment of this subject, accompanied by careful tests, came in 1910 from the hand of Th. v. Kármán, then in Göttingen.† His contribution is one of the most important in the whole vast literature on the subject of columns.

Prandtl and, after him, Hencky have succeeded during the last few years in analyzing the state of stresses and deformations occurring in certain cases of plastic action when one body penetrates into another.‡ Nádai has analyzed cases of torsion beyond the proportional limit.§

Charles Terzaghi, M. Am. Soc. C. E., has attacked the fundamental problems of the mechanics of soils.|| Strikingly interesting is the mutual influence found here of the state of stress and the movement of water. A problem in strength of materials becomes hydraulics.

Finally, may be mentioned an exceptional piece of work, theoretical and experimental, by A. Brandtzaeg, presented in a thesis at the University of Illinois, in 1926.¶ The subject is compressive strength of concrete. Following and developing a procedure introduced by R. Böker in 1913,\*\* he applied methods of statistical mechanics to a solid consisting of crystalline parts with planes of weakness distributed by laws of chance in all directions. He succeeded in this way in accounting for a part of the curved portion in the stress-strain diagram, and he explained a number of the phenomena which he found experimentally in cases of three-dimensional states of stress. Here, surely, the subject of strength of materials is in a new phase of development.

\* Concerning this and other modern applications of the theory of elasticity, see the article by L. Föppl, "Neuere Fortschritte der technischen Elastizitätstheorie," *Zeitschrift für angewandte Mathematik und Mechanik*, v. 1, 1921, pp. 466-481.

## THE PRESENT

It is by no means discouraging to consider the state of affairs in structural mechanics of the present day. Group enterprises of many kinds are promoting research and distributing knowledge. Think, for comparison, of the situation 150 years ago when only a few learned academies performed these functions. Now engineering societies, schools of engineering, and some periodicals do much to make research possible. One periodical of this kind should be mentioned especially. It is the *Zeitschrift für angewandte Mathematik und Mechanik*, published since 1921. Its editor is a man of unusual caliber, Professor R. von Mises, of Berlin. The German periodical, *Der Bauingenieur*, published since 1920, also deserves notice.

In the spring of 1924, largely due to the initiative of Professor C. B. Biezeno, of Delft, a "First International Congress for Applied Mechanics" was held in Delft, Holland. The *Proceedings* published the following year contain much material of practical and scientific value. A Second Congress was held in September, 1926, in Zürich, Switzerland.

A recent enterprise of great value is the "Encyklopädie der mathematischen Wissenschaften", of which Volume IV, which consists of four sub-volumes, has the title "Mechanik". Volume IV has been completed except for a part of Sub-Volume 2. The plan of this encyclopedia is to summarize all the important work of the field.\* Another similar enterprise has been started very recently under the title "Handbuch der physikalischen und technischen Mechanik".†

Among the individuals representing structural analysis at the present day, there are some stars of considerable magnitude. Among them four may be mentioned: L. Prandtl and Th. v. Kármán, in Germany; A. Ostenfeld, in Denmark, and S. Timoshenko, formerly in Russia, but since 1922 in the United States. They are men of broad scholarship and creative imagination.

The work of Dr. Timoshenko brings to attention the Russian tradition, of which he is a contemporary representative. One may trace this Russian tradition back to the days of Euler and his influence through the St. Petersburg Academy. Dr. Timoshenko's presence in this country is a reminder, at the same time, of the international character of the science of structural mechanics.

Structural analysis is, of course, intimately allied with and dependent on structural testing. The United States has excelled in the latter field. The grand scale of this experimental work, and the determination to find out, have aroused the admiration of Europeans. In structural engineering this country has also excelled. In structural analysis, it has done well, yet the great ideas have come mainly from Europe.

Hope for future advance in structural analysis lies in the fact that the subject, international as it is, fascinates many in all parts of the world.

\* The article by L. Henneberg, in Sub-Vol. 1, and those by Th. v. Kármán, M. Grünig, and K. Wieghardt, in Sub-Vol. 4, are of especial interest in connection with structural analysis.

† Edited by F. Auerbach and W. Hort and published in Leipzig, Germany.

## DISCUSSION

S. TIMOSHENKO,\* Esq. (by letter).—It is a consequence of the ancient structural project at Babel (as the story goes), that linguistic barriers have hampered the progress of science. These barriers have become of slight concern to the English speaking peoples with reference to many of the languages, especially French and German, but, unfortunately, the Russian barrier is not so easily surmounted. The writer takes this opportunity to help remedy this, and to elaborate the reference made to the Russian tradition.

The development of structural analysis in Russia begins with the work of Daniel Bernouilli, who was invited there in 1725 by Catherine I, and was appointed to the Professorship of Mathematics in the Academy of St. Petersburg. Bernouilli was the first to obtain the differential equation of the deflection curve of a prismatic bar. He arrived at this by a consideration of the transverse vibration of the bar.† To his inspiration may also be credited the investigation of elastic problems by L. Euler (1701-83) who in 1733 succeeded Bernouilli in the Chair of Mathematics at St. Petersburg. Euler's most important contribution to the theory of structure is his discussion of the buckling of columns subjected to axial compressive forces. He treated not only the case in which the load is applied at the top of the column, but also the effect of the weight of the column. He was also the first to investigate the bending of bars originally curved. He introduced the assumption that the bending moment in this case is to be taken proportional to the difference between the original and the new curvature. This assumption was proved later by considering the nature of the elastic forces.

At the beginning of the Nineteenth Century the development of the theory of structures in Russia was greatly influenced by two Frenchmen, Lamé and Clapeyron, who were professors in one of the oldest Russian engineering schools, "The Institute of the Engineers of Ways of Communications". This school was opened in 1807 and later had a prominent rôle in the development of engineering education in Russia. Professor Jouravski of this school was in charge of the building of the first railway bridges in Russia and was one of the first to develop methods of determining the forces in members of a truss. The Ministry of Ways of Communication was skeptical about his conclusion that in the Howe truss the forces in the verticals (bolts) produced by uniformly distributed load increase from the middle of the span to the supports. In order to demonstrate his theory, Jouravski used an interesting model. The verticals were replaced by strings and from the tones of these when plucked, the stress differences were readily shown.

He gave also the elementary theory of shearing stresses in beams, which is now found in all books on strength of materials.‡

As concerns curved bars, H. Golovin was the first to give an exact theory of the bending of curved bars of a rectangular cross-section.§ His work, pub-

§ *Bulletin*, Technological Inst., St. Petersburg, 1881.

lished in Russian, remained unknown in Western Europe, and his solution was later rediscovered by L. Prandtl in Germany\* and by Ribière in France.†

The theory of elastic stability was advanced considerably by the work of Professor F. Jassinsky of the previously mentioned Russian engineering school. He developed‡ the theory of the buckling of bars having elastic lateral supports and applied this theory to the investigation of the stability of compressed chords of through span bridges. To Jassinsky engineers are indebted also for the correct solution of the problem of the buckling of bars compressed beyond the yield point. His books on the mathematical theory of elasticity and on the theory of structures also had a great influence on the development of the teaching of these sciences in Russian engineering schools.

Among the Russian engineers of the beginning of the Twentieth Century may be mentioned A. N. Kriloff, who made considerable progress in the theory of vibration of bridges and ships§ and I. G. Boobnoff who became prominent because of his work in the theory of the structure of ships.|| He gave a very complete treatment of the bending of rectangular plates submitted simultaneously to hydrostatic pressure and to tension in the middle surface. Boobnoff was also the first to give an accurate solution of the problem of bending in rectangular slabs with built-in edges.

ALFRED D. FLINN,¶ M. Am. Soc. C. E. (by letter).—Professor Westergaard's condensed and well co-ordinated summary of the successive steps along the several important lines of structural analysis, should be stimulative and helpful to further progress. It is a convenient and interesting historic narrative and annotated bibliography; but it is more. Professor Westergaard has produced an orderly series of skillful, critical, and lucid analyses of the contributions of the several distinguished workers in the field, who have made modern methods of structural analysis feasible. This summary illuminates the subject, makes relationships apparent, and indicates need for further researches.

The paper also emphasizes the facts that modern engineering is truly a learned profession and that it demands a rigorous educational preparation. That much vaunted "horse sense", if untutored, is no longer safe or sufficient equipment for the design of present-day structures to which human lives, limbs, and fortunes are committed. Adequate preparation for the practice of such engineering demands, also, better teaching than has been offered by some engineering colleges in years gone by.

JACOB FELD,\*\* Assoc. M. Am. Soc. C. E. (by letter).—In summarizing, in such compact form, the original contributions to the science of structural analysis, the author has presented a study which ranks in value far above the

usual historical scientific paper. Although no attempt was made to explain the methods of attack of the men whose contributions are mentioned, the results as applicable to structural analysis as well as the effect of one man's work upon succeeding generations are clearly outlined. In spite of the enormous amount of historical data, the paper is written in a style which makes interesting reading. The addition of footnote references to the more important contributions makes this paper quite valuable as an outline for the research student in this field. It is to be hoped that it will be given widespread distribution among students and research workers.

The paper deals entirely with theoretical analysis as applied to structural design. It would be interesting to have a parallel discussion of the experimental work contributed by a great number of the men whose names are mentioned by the author, as well as by others, which has been used to check the theories proposed and to put the study on a scientific basis.

The discussion deals chiefly with statics, that portion of structural analysis which is used mostly by the membership of the Society. However, a great number of the contributions mentioned are really only special cases of the general theoretical discussions of dynamic principles. Considerable simplification has resulted in the very complicated equations for the general solutions of most dynamic problems by the use of vector notation and vector processes. This is merely a method of reducing the mechanical labor in mathematical derivation or a new method of placing certain ideas in symbolic form. The resulting vector mechanics has been applied in the mechanical and electrical fields as well as in the aerodynamic field. However, the recent expansion of structural design to the work required in airplane and airship production practically necessitates the inclusion of the general dynamic principles in the list of contributions to the field of structural analysis. The application of stress analysis for non-homogeneous bodies, such as reinforced concrete, has found a fertile field in the design of airships of various combinations of rigid keels and non-rigid envelopes. It is found that a great number of very theoretical contributions in stress analysis are quite applicable to the actual design of such structures.

Although separated in the text, the work in elastic stress by Cauchy and by Lamé are complementary, and together they give the general solution of the magnitude (by Cauchy) and of the direction (by Lamé) of stress. The results, analytically, are quite complicated; considerable simplification has been introduced by Föppl by the use of vector notation.

The author has omitted a fairly important contribution to the subject of elasticity based on the so-called energy function. On this basis, Kirchhoff and Helmholtz independently showed that an isotropic elastic body can be defined completely by two elastic constants, the modulus of shear or rigidity, and the bulk modulus of elasticity. Experimentally, the latter constant was studied by Karman.\* His work on small cylinders subjected simultaneously to hoop and longitudinal pressures supplements his work on columns of ductile materials mentioned by the author. Following the same idea of the energy function, S. E. Slocum, M. Am. Soc. C. E., has derived general formulas for the

\* *Zeitschrift des Vereines deutscher Ingenieure*, Vol. LV, 1911, pp. 1749-1757.

shearing deflection of beams of arbitrary, variable, or constant cross-section and also a general formula for the torsional deflection.\* Most of the relations in indeterminate structures can easily be deduced from the idea of the energy function.

It is quite surprising to find how much repetition there is in names of contributors in the field of structural analysis and in that of soil mechanics.† Both subjects seem to start with the same man, Coulomb, although previous work by a great number of men had paved the way. Just as Navier, Cauchy, and Poisson founded the theory of elasticity, Navier in his generalization of Coulomb's theory in 1826 to the cases of surcharged walls and also to the cases of soils containing cohesive as well as frictional resistances, and Cauchy and Poisson (whose works were the bases of the earth pressure theory by Maurice Levy, Saint-Venant, and Boussinesq), can be classed as the founders of the present two schools of soil study.

It is seldom realized how much progress in scientific study has been lost because of poor translation or the inclusion of the translator's own ideas into a book which bears the name of the original author. As a result, discrepancies will often be found in the reported contributions of certain men to any one subject, and it is quite important that the original references be consulted for a true evaluation. In this respect, Professor Westergaard's paper is especially good and, therefore, reflects considerable credit upon its author.

H. M. WESTERGAARD,‡ M. Am. Soc. C. E. (by letter).—The writer has read with interest and appreciation the discussions by Professor Timoshenko, and Messrs. Flinn and Feld. Indebtedness is expressed to Professor Timoshenko for his account of the Russian tradition.

The writer does not understand the remark by Mr. Feld about Cauchy and Lamé. His reference to an investigation by S. E. Slocum, M. Am. Soc. C. E., published in 1911, to determine the influence of the shearing stresses in beams upon the deflections, by consideration of the energy, may be supplemented by the statement that W. Ritter solved the problem in 1888 by a simpler consideration of the energy, and that R. Land presented a particularly satisfactory simple solution of the whole problem in 1894.§

Professor Timoshenko referred to the work of Boobnoff in the theory of the structure of ships, and Mr. Feld mentioned the structural problems in aeronautical design. It is significant that the applications of structural mechanics extend to many fields of engineering. In aeronautical design the emphasis on economy of weight has led to new problems, involving, especially, the possibility of failure by buckling.||

|| For example, on the subject of wing-beams, see, H. Reissner and E. Schwerin, "Die Festigkeitsberechnung der Flugzeugholme," *Jahrbuch der Wissenschaftlichen Gesellschaft für Luftfahrt*, v. 4, 1916; H. Müller-Breslau, "Graphische Statik der Baukonstruktionen," v. 2, sub-vol. 2, Second Edition, 1925, pp. 647 and 661; and Joseph S. Newell, *Am. Soc. C. E.*, "The Design of Airplane Wing-Beams," *Proceedings*, Am. Soc. C. E., March, 1928, *Papers and Discussions*, p. 725.

Professor H. Reissner, of Berlin, Germany, in a letter to the writer, expressed the view that certain chapters in the history of structural analysis might well have been included in the paper, or dealt with more fully. He mentioned the following subjects: Vibrations,\* buckling,† airplanes, and experimental devices for structural analysis. The writer agrees with Professor Reissner, but wishes to add that many more subjects might have been included.

Referring to the experimental devices, the introduction of the use of polarized light by A. Mesnager, for the purpose of determining stresses, was mentioned in the paper, but it should have been stated that E. G. Coker has done eminent, extensive work with this method‡. The use of models with the devices invented by George E. Beggs, M. Am. Soc. C. E., was mentioned in the paper. The soap film analogy according to L. Prandtl, for the study of torsion of non-circular members, was also mentioned. This analogy has been supplemented by a roof-and-membrane analogy indicated by A. Nádal, whereby one may study, experimentally if one wishes, the progress of plastic action or yielding that must take place in a non-circular member subject to torsion.§ Lydik S. Jacobsen has devised a simple and effective method of determining the stresses produced in a circular shaft with variable diameter by measuring electric potentials in a plate of non-uniform thickness.||

The subject of secondary stresses in trusses might well have been discussed in the paper. At this place, it will be sufficient, however, to refer to the notable paper on the subject by Cecil Vivian von Abo, Assoc. M. Am. Soc. C. E., which contains an historical discussion.¶

An important principle, which was not mentioned in the paper, was stated by Melan in 1888, and applies to suspension bridges.\*\* A heavy chain possesses flexural resistance by virtue of its weight. Applying this structural principle to the bridge, one finds that the stiffening trusses are aided by the dead load.

In concluding, the writer wishes to call attention to a recent development in the theory of beams. In order to deflect vertically, without twisting, a channel used as a beam with the web vertical should be loaded so that the resultants of the loads lie in a certain vertical plane. This plane does not

\* It is proper to mention in this connection the following paper by H. Reissner: "Schwingungsaufgaben aus der Theorie des Fachwerks," *Zeitschrift für Bauwesen*, v. 53, 1903, Columns 135-162. On the general subject of vibrations, see, W. Hort, "Technische Schwingungslehre," 1922 (Bibliography on vibrations of trusses, p. 802), and S. Timoshenko, "Vibration Problems in Engineering," 1928.

† A bibliography on the subject of buckling may be found in *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 850. The following more recent investigation should be mentioned: R. v. Mises, "Ueber die Stabilitätsprobleme der Elastizitätstheorie," *Zeitschrift für angewandte Mathematik und Mechanik*, v. 3, 1923, p. 406. The same volume contains four other notable papers on buckling.

contain the centers of gravity of the cross-sections, nor the centers of the web, but is found outside the beam behind the web. The strikingly simple explanation was found by A. Eggenschwyler\* and R. Maillart.† In the cross-section one finds vertical shearing stresses in the web and horizontal shearing stresses in the flanges. The resultant of the horizontal shearing stresses is a couple, which, combined with the resultant of the vertical shearing stresses, gives as the resultant of all the shearing stresses a vertical force lying in a plane outside the beam. The resultants of the loads, obviously, must be contained in this plane, if the beam is to deflect without twisting. Tests‡ with steel channels have shown this conclusion to be accurate, but one may also perform the experiment convincingly with a model made of cardboard. It is strange that a structural principle so simple and important, and so easy to demonstrate, should have remained unnoticed until only a few years ago.

Paper No. 1728

### EVALUATION OF WATER RIGHTS\*

BY JOHN E. FIELD,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOSEPH JACOBS, FRED H. TIBBETTS, CHARLES R. HEDKE, FRED C. SCOBAY, LYMAN E. BISHOP, R. L. PARSHALL, S. H. STIVERS, C. E. GRUNSKY, AND JOHN E. FIELD.

#### SYNOPSIS

The methods and conclusions given in this paper are based on twenty years' experience in making appraisals wherein the value of water rights was an important part. This has involved water values in excess of \$10 000 000.

#### APPRAISALS ON NEW PROJECTS

Somewhat related to an appraisal is the estimated cost of irrigation works. The question of the tangible, physical, and water values back of the bonds always arises in the event of financing. In the case of a new district, these are largely estimates and generally involve the taking up of new rights. Their value at the time of filing is almost nil, so that the value of a proposed project is generally limited to the physical works, to the rights of way, including interest during construction, and to organization expense, etc.

On some of the projects with which the writer has been connected, old water rights were purchased, including old reservoirs, reservoir sites, and old canals. In such cases appraisals were required for the works purchased, particularly for the value of the water itself.

\* Presented at the meeting of the Irrigation Division, Denver, Colo., July 14, 1927. The author suggests that the discussions by M. C. Hinderlider, R. I. Meeker, Lynn Crandall, and E. B. Debler, Members, Am. Soc. C. E., on the Symposium on Administrative Water Problems (which follows his paper), be read in connection therewith in order to clarify the laws and practices of the Arid States on this subject.

† Denver, Colo.

The new works generally destroyed or replaced old ones, the water being used over the entire new system. At the time of purchasing old works, and primarily to obtain the old water rights, whatever amount was paid for those portions of the old works that were abandoned or destroyed, was added to the cost of the water or water right.

#### EARLY APPRAISALS

The writer's early appraisals were based almost wholly on data gathered concerning the actual sale and transfer of water, a rather simple matter. Furthermore, it was found that there was a general impression in every locality as to how much water was worth. This influenced the appraisal. These opinions included, not only the value of the water right itself, but of a proportionate interest in the works. On some canals, construction costs are far more than the value of the water itself. On other canals, the physical works are simple and of very low cost. Hence, it must be borne in mind in speaking of the value of water that the physical values of the works and of the water itself must be separated.

#### SIMILARITY IN VALUES

The market value of an acre-foot of water in a given locality does not vary whether its use be domestic, manufacturing, or agricultural. Further, stored water has little more value than unstored water. A proviso, however, is essential to this last statement, namely, that the use of the unstored water must be economical and beneficial.

Consider in the abstract an acre-foot of water. It may be easily obtainable during the flood season, yet in the absence of other acre-feet, procurable at other times and necessary to bring the crop into the flood period and later carry it to full maturity, that acre-foot of flood water would be without value. If, however, it entered into the production, in whole or in part, of a crop between seeding and harvest, it has a value almost, or quite, equal to the value of an acre-foot used at any period of crop growth. The use of flood waters means, generally, a saving of the stored supply. The law of supply and demand alters the prices, of course; but intrinsically, and on the basis of crop production, the value of flood water is as great as that of water obtainable during the low flow period.

The conclusion as to the uniformity in value of water may be startling to some engineers. Except for the need of water for agriculture in the semi-arid region, there would be enough for domestic needs and for manufacturing. The water used for agriculture can be purchased and converted to a domestic use, it can be condemned and appraised at its agricultural value. It is agriculture, therefore, causing, as it does, a demand in excess of the supply, that gives value to water. It is a more largely consumptive use than either of the other two, although in both manufacturing and domestic supplies, the consumptive use is much greater than is generally believed.

The writer has investigated consumptive use by the City of Denver, Colo., and has concluded that during the summer months about 66% of the gross

diversions was returned, while in the winter the quantity was 80 per cent. As regards the consumptive use of water for manufacturing purposes, principally for cooling, about 10% of the supply was lost in transit through the power houses and mills. The idea that practically all the domestic and manufacturing supply returns to the river is just one of those dreams that does not come true.

The value of water for domestic purposes should not be based on the city's necessities, nor on what the city could afford to pay, but rather on the value of water for agricultural purposes. As to manufacturing, the great intrinsic value lies in the water used for condensation purposes. Large generating plants are often forced to go to localities where water is available rather than to build on sites in all respects preferable, except that the agricultural interferes with the manufacturing use. If the water is used for the direct generation of power the value could be determined by comparison with the cost by steam or the use of electric power.

The statement that an acre-foot of water, whether stored or direct flow, varies little in value, is not so obvious as the first conclusion. It is true that an acre-foot of water in the latter part of the season is much more valuable than in the early and flood periods, and that an available quantity of water during the time of very low flow is much more valuable than during the flood period. This is confirmed by the variations of value of water having different dates of decree.

Obviously, flood rights are of considerable intrinsic value. They permit a greater area to be cultivated, encourage the growing of early maturing crops, and stimulate a more general rotation of crops than would otherwise be practiced. Reservoirs built for the storage of water are generally much more expensive per acre-foot of capacity than are canals. Deducting the cost of structures from the value of water plus structures would show that water values are more nearly equal than the values of structures plus water. In the two types the cost of a dam with its accessories often approaches the value of water plus structures even after it is fully used and is a successful and going concern. Thus, waters having decrees for storage purposes and for direct use have values varying with the dates of decree and independent of the method or character of works used in securing it.

In his early experience in appraising water rights, it seemed to the writer to be simply a matter of ascertaining the sale value of the water as determined by a number of sales under comparable conditions and in the same locality. The use of such data, however, led to the most irreconcilable differences as well as to absurd results. It soon became apparent that there was a vast difference in value between water "direct-flow" as compared with "stored water". In some cases, the opposition engineers insisted on converting one into the other, and basing the value on the quantity theoretically procurable during the entire irrigation season. While such a method appeared ridiculous at that time—and, indeed, the results were ridiculous—yet it now appears that it is, in part, correct. Due regard, however, must be given to the quantity actually produced by each and to the date of the decree. To

judge stored water by comparing it with value of water diverted under old decrees, or *vice versa*, although the time of use and application were the same, would be wrong. The cost of structures in each case added to the water value gives that generally quoted.

#### APPARENT AND TRUE VALUES

To those familiar with the transfer of water in Colorado from one ditch to another, the purchase price is not a true measure of the value. In most cases there are conditions and provisions in the agreement which very materially alter the given value. The purchase of 10 sec.-ft. of water at \$3 000 per sec.-ft. is \$30 000, but when to this figure are added the Court costs of several thousand dollars, and the cutting down of the quantity allowed to be transferred, the rate might be, and usually is, more than doubled. Where water rights are purchased and transferred, it is almost invariably true that the seller is anxious to sell and the purchaser is not compelled to buy; that whatever that seller gets for his surplus water is so much net money to him. Too frequently, he is selling something he has never used or, at best, something that he at one time used but through changed conditions, due to seepage returns, etc., he no longer needs.

#### THE METHOD PROPOSED

In an effort to reconcile these differences, the writer sought a more rational method for the determination of the value of a water right. In one case, he selected three of the larger, more substantial, and well-known ditches on the Arkansas River—ditches on which not only were the values of the structures known, but for which the daily flow into the canals over a period of at least eight years was of record. As each of the three canals has a number of priorities of different dates, varying not only as to their own rights, but as to those of the other two ditches, the appraiser was able to construct curves showing value and priority dates.

In this case about 200 priorities and more than 100 diversions were to be appraised. The uses were: Domestic, the year round; manufacturing, some used intermittently and some continuously; and, agricultural, where the irrigation season varied from 60 to 300 days in the year. Also, the records for the domestic and some of the manufacturing uses were expressed in gallons per year without reference to the maximum flow or the hours or days when the pumps were in operation. Therefore, it was necessary to develop curves showing the value of different priorities and the percentage of their efficiency as compared with a 365-day use. It was also necessary to use total volumes diverted during the year, expressed in acre-feet, rather than the irrigation season and the rate of flow expressed in cubic feet per second.

It was decided, therefore, to use as the maximum possible, the theoretical quantity that could be diverted under the decree, and to determine the percentage of efficiency or delivery by comparing the actual delivery with this theoretical maximum.

First, the selling price of a share in the ditch company was ascertained. For each ditch the price had been quite uniform over a period of four or five years, and several transfers of comparatively large blocks of stock had been made. Furthermore, whether the stock was sold in quantity or in individual shares, the price varied little. The value of the works, including the water rights, was determined by multiplying the average sale price by the number of shares. From the books of the companies and from personal investigations on the ground, the writer determined the replacement value of the structures, making due allowance for the fact that some parts, embankments in particular, were more substantial and valuable than when they were first constructed, having passed safely through the most dangerous period of their existence, namely, the first few years. Having determined the structural and going-concern value, as well as the full value of the works, the difference between the value of the stock and the value of such works was called the value of the water rights.

In reality, the three ditch systems are mutual ditch companies in which the water users own non-interest bearing shares roughly proportioned to the area irrigated, or to the necessity of the users. Generally speaking, stock is sold only to users, and the proceeds are used for the payment of debts, for improvement, or for the reduction of assessments. The ownership of shares without land on which to use the water would simply mean annual assessments without benefit.

Next, the quantity of water carried by the three canals was ascertained over a period of eight years. A longer period would have been desirable, but the records were not uniform beyond that period; indeed, many were missing, so that, perforce, study was limited to eight years. Having ascertained the average number of acre-feet of water diverted per annum, the value per acre-foot was determined by dividing the water-right value by the number of acre-feet diverted. An example, taken from the report, will show clearly the method used:

"FORT LYON CANAL

"Priorities are	April 15, 1884	for	164.64	cu. ft.
	March 1, 1887	"	597.15	" "
	1893	"	171.20	" "

The value of this system is, according to its President, \$6 000 000, and that of the structures about \$2 000 000, leaving the water value as \$4 000 000, with \$600 000 of indebtedness, a total value of \$4 600 000.

A careful analysis of the daily records for eight years shows the flow credited to the respective priorities to be as follows:

From reservoirs .....	47 000	acre-ft.
Average for the 1884 decree.....	80 000	" "
" " " 1887 " .....	90 000	" "
" " " 1893 " .....	8 300	" "

Total..... 225 300 acre-ft.

The value of the water per acre-foot is, therefore..... \$20.42

Reservoir water =  $47\,000 \times \$20.42 = \$960\,000$ .

Decree, 1884, therefore, is worth  $\$1\,635\,000 = \$9\,925$  per cu. ft. per sec.

" , 1887, " " " 1 838 000 = 3 080 " " " " "

" , 1892, " " " 169 000 = 990 " " " " "

The 1884 decree delivers 80 000 acre-ft. out of a possible 119 200, for 365 days during the year. Its percentage of efficiency is, therefore, 67.15. Therefore, \$9 925 represents 67.15% of the maximum value; that is, 100% would be worth \$14 900 per cu. ft. per sec. Similarly, the other priorities give the same result: The 1887 decrees have an efficiency of 21%, and the 1893 decrees, one of 6.7%, for this particular canal. In case the value of the physical works was placed too high, the value of the priorities would, of course, be greater than that shown.

In ascertaining the number of acre-feet delivered under each of the decrees on the canals, the daily records were studied, and whenever only the oldest decree was being filled or partly filled, the entire quantity was assigned to the first decree. When a quantity was shown in excess of the first decree, but not greater than the first and second combined, the remainder was assigned to the second decree; whenever the quantity carried was in excess of the two first decrees, the excess was credited to the third decree; and so on through all the decrees. The result of this study was that the writer had the average number of acre-feet delivered per annum by each decree, and multiplying that quantity by the acre-foot value as determined gave the value of the decree. Dividing this by the quantity of the decree, in second-feet, gave the value per cubic foot per second. As the values were to be used in comparison with supplies for domestic use, for manufacturing power, and for irrigation, and with stored and unstored water, it appeared necessary to have some common basis for comparison. The quantities diverted under each priority varied in amount from day to day and from year to year. The only common ground seemed to be what would have been the quantity diverted had every priority run for the entire year.

#### GROUPING PRIORITIES

Having ascertained by this method the value of ten or twelve priorities on the river, it is possible to construct a curve that can be used in determining values of other decrees. In the case used as an illustration it was shown that all priorities having a date earlier than 1874 were of equal value. That this was true was demonstrated by plotting all the priorities as to date and quantity, the quantities being the aggregate of the water decreed prior to a certain date. In this way, it was ascertained that even in years of minimum flow the supply in the river was in excess of all the decrees of 1874 or earlier. It was found, also, that priorities could be grouped. These groups were separated by some decree calling for a very large quantity of water. Thus, the application of the data and the determination of the value of specific water rights were much simplified.

In Fig. 1 the curve to the left relates in part to the three canals investigated and to their actual value as determined, while the several curves to the right represent values as determined from the sale of water to be transferred,

illustrating the impracticability of using that method for the determination of real values. These latter curves illustrate, also, the gradual increase in values of water rights over a period of years.

Starting at zero on the year of appropriation, they rise uniformly to the time when the first information is available, about 1897; from that point the actual sale prices indicate quite a uniform advance in values, a sudden rise during the World War period, with no rise, possibly a decrease, subsequent to about 1921. The steepness of the curve between 1900 and 1905 is probably due to the effect of the Reclamation Act, while the break in the curve in 1907 is probably due to the financial panic of that year. However, one is not justified in using this curve as anything other than illustrative.

It should be clearly understood that this method is suggested for the purpose of laying a foundation only, for detail study. On each stream the value must be determined independently of that on any other system, but even after having obtained a basis for further detailed work, it should be used more as a guide and to permit the construction of curves where many data are missing.

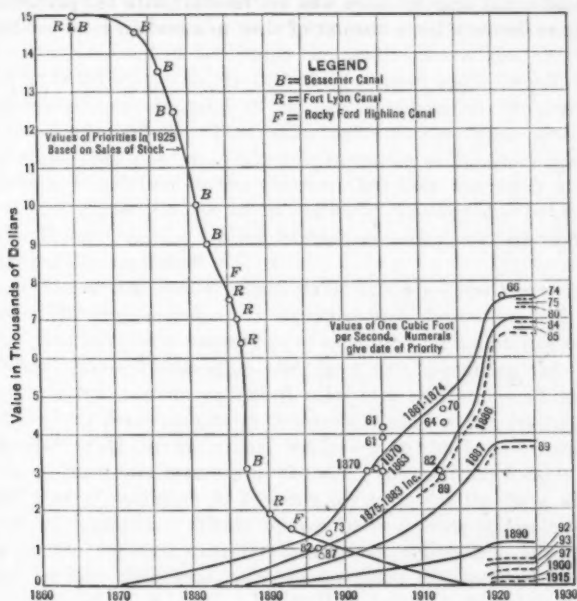

FIG. 1.

The law of supply and demand rules, and it often happens that under an old priority, where there is an abundance of water, the value of the water is less than under a later priority, where the abundance of land makes a marked demand. The matter of crops, productivity of the soil, the markets, all these must be taken into consideration by the appraiser in his detailed study. In

arid and semi-arid regions the value of the water is its value for its most important use, namely, for irrigation. Therefore, the appraiser may determine from curves based on agricultural use the value of the domestic water rights for cities, and the value of water for railroad purposes. In the latter case, however, it often happens that the value of the water is the cost of bringing in some substitute which might involve hauling for long distances. Where water is as scarce as this, however, a value could hardly be established under the method suggested.

Colorado is fortunate in having a law which requires the installation of automatic registering devices on all canals. Since that law was passed the State Engineer has exercised diligence in having automatic registers placed throughout the State. When the records from these are matured and available, it will be an easy matter to ascertain the stock value of an irrigation system and the average number of acre-feet diverted per annum and from this to deduce the value of an acre-foot of water. It will involve no great amount of labor to place the proper values on water rights. As has been stated, this can be done safely only by those who are familiar with the particular locality or willing to devote a large amount of time to ascertain local conditions.

## DISCUSSION

JOSEPH JACOBS,\* M. AM. SOC. C. E. (by letter).—This paper is of value and interest because it deals with a subject that grows in importance each year, in accordance with a steadily expanding population, agriculture, and manufacturing industry and their persistent demands for additional water supplies. It seems to deal, not with the broad, general subject of water-right valuation, as its title implies, but rather with a restricted phase of it which has to do more particularly with the relative values of several irrigation water rights in the same mutual ditch system, but under decreed differences as to priorities and quantities of water.

It is frequently contended, in the valuation of public utility properties, that no allowance should be made for water rights, because the actual ownership of the water rests with the public, and there have been many findings and rulings by public service commissions sustaining this view. As against allowing nothing for the water right, a more equitable showing could be made for the principle of dividing the water-right value between the public and the utility owner, in cases where the water-right value is based on consideration of the extra cost involved in developing the next best available water supply. This would be based on the theory that the consumer public would otherwise lose, completely, the money value of its natural advantage of location with respect to the cheaper supply. That water rights do have value, however, and that this shall be recognized as a principle in public utility valuations, unless there is definite stipulation to the contrary, has been too often attested in decisions of the higher Courts to be seriously questioned. In the recent Indianapolis Water Case the United States Supreme Court stated that "the water rights must be included".

Further evidence that owners attach value to their water rights inheres in the history of the violent and costly struggles and encounters, both physical and judicial, that have been engaged in to establish and maintain such rights.

The Federal Power Commission also, in a way, recognizes this principle of water-right value. In its published rules and regulations which provide (in respect to power developments on Government land within its jurisdiction) that the licensee shall pay an annual fee, based on the installed capacity of the plant up to the power capacity of the site, ranging from 5 cents per h. p. for the first year of operation to 25 cents per h. p. for the third and subsequent years of operation. These figures have definite capitalized values, depending on the assumed earning capacity of money and, with a known power head for any given case, such values could be expressed in terms of dollars per second-foot of water. While it is believed that thus basing the charge on plant capacity may indicate recognition, by the Commission, of the principle of water-right value, the charge is not, of course, a measure of such value. In the first place, the Commission states that the charge is "for reimbursing the United States for the cost of the administration of the act." In the second place, the charge may be considered as being in part for rental

\* Cons. Engr. (Jacobs & Ober), Seattle, Wash.

of land occupied by the project and, if the available water supply is in excess of any possible power-market demand, it may be regarded as attaching more to the power franchise than to the water right, because such a distinction can be made.

It is less difficult to prove that water rights have a value that should be recognized, than it is to determine what that value is. The valuation method to be used, and the final value to be determined, depend in part on the purpose of the valuation; in part on whether a private industry or a public utility is being dealt with; and, finally, on the elements that make up the value of the water right. It is not possible to formulate a simple definition of what these elements are because of the many qualifications and exceptions that have application to specific cases. Moreover, by reason of statutory differences, what may be valid in one State, respecting water rights and their valuation, may not hold in another State. There are numerous factors that have a bearing on water-right valuation. Some of the more important of these are:

- (a) The State laws and regulations on which the validity of the water right rests.
- (b) The priority, amount, and duration of the water right as defined by Court decree or as affected by franchise provision. This involves also the question of storage rights as distinguished from normal-flowage rights.
- (c) The franchise, and the limitations thereof, under which is operated the project to which the water right attaches. A short-lived franchise would detract from the value of a water right and the franchise may even stipulate that no value shall attach to the water right under certain conditions.
- (d) The amount that was legitimately expended, by purchase or otherwise, in securing the water right.
- (e) The value, for agriculture or other ordinary purposes, of the land occupied in the development of the water right as, for instance, the land required for dam, power house, canal head-works, etc.
- (f) Whether or not the project to which the water right attaches is fully or only partly developed and whether the market for the product that the project supplies is immediate or only prospective and whether it is permanent.
- (g) The abundance of the water supply. A supply in excess of present and prospective market requirements would tend to depreciate, as would a restricted supply tend to appreciate, the unit value of a water right.
- (h) The cost of the next best available water supply or other adequate substitute.
- (i) A possible higher-valued alternative use for the water.
- (j) The capitalized value of net earnings of the project above operating expense and normal interest return on the investment in the physical plant.

The bearing of most of these considerations on the value of a water right is too obvious to require comment, but a brief further discussion of some of them may be desirable. Referring to Item (d), it would seem that while the amount that was legitimately expended in securing the water right would not necessarily fix its maximum value, it would normally fix the minimum value that should be allowed. The word, "normally," is used because if the condi-

tions surrounding the business were such that it was impossible to earn a fair return, regardless of rates, and such instances can be cited, then the water right might have no value at all. The Item (e) consideration affords another criterion of value. If the value, for ordinary purposes, of the land required to utilize the water right, is deducted from the actual price paid for the land, or if it is deducted from the value of the land for ordinary purposes multiplied by the average public utility factor that obtains in the district, in connection with real estate purchases, then the remainder may be regarded as one measure of the value of the water right. This, however, is not deemed to be a rational or dependable method of water-right valuation because of the uncertainties and the fortuitous circumstances that affect the "public utility factor". In many instances the land has no value at all for ordinary purposes.

In respect to Item (f) it may be said that the status of the project, as to the extent of its development and the character of its market, must be reflected in the value of the water right, although it is believed that these factors would be more fully and more properly reflected in "development cost" and "going concern value", if the intangible elements of value in a property were segregated instead of being combined into a single item, as is so frequently done. While a developed project with good markets for its product would tend to give substantial value to a water right, no Court would be inclined to concede a material present value to such right on account of a prospective future market unless that market was definitely assured and reasonably close in point of time.

In connection with Item (g) which indicates that the magnitude of the water supply, in relation to demand, affects the water-right value, a distinction between intrinsic value and commercial or market value must be recognized. In the semi-arid States, for instance, irrigation water has intrinsic value because agriculture would be impossible without it, but, even if the results of this agriculture are highly profitable, it does not necessarily signify that the water right is of high commercial value. If the available water supply is in excess of possible demands, and is obtainable from the State without cost other than nominal filing fees, then, manifestly, the water right proper could have no great commercial value, for no one would pay a high price for that which he can obtain practically for nothing. Such value as was warranted by the net profits from the agriculture served, would be reflected mostly in the land and, according to the extent that it was reflected in the stock of the ditch company, the value of the latter, in excess of that represented by physical plant investment and development costs, would more properly attach to "going concern value" and to "franchise value" than to water-right value. If, however, there was not an abundance of water for future or other requirements then the water right would properly absorb a greater part of the excess value previously mentioned.

The cost of the next best available water supply or other adequate substitute and the possible higher valued alternative use of the water, referred to in Items (h) and (i), not only afford distinct bases for determining the value of a water right, but they may, in certain cases, become the controlling considerations. Certainly, they would have application in dealing with water

supplies for private industries and, in connection with public utility properties, they would, ordinarily at least, fix the maximum allowance that could be made for the water-right value. If the water right may appreciate in value, or attain maximum value, from these considerations, a logical corollary would be that if in the future, through changed conditions in stream run-off, or through new scientific developments, a substitute may be provided at lesser cost, then the value of the old plant would depreciate and this loss in value would also, in part, be reflected in the water right.

The most fundamental consideration, the one that has the most general application, is that defined in Item (j). The capitalization of the excess net earnings mentioned, measures not the value of the water right alone, but of all those elements classed as "intangibles". If there is no such excess, actual or prospective, then, from an investment standpoint, no value could be assigned to the water rights or other intangibles, and the allowed value for a property would need to be assigned wholly to its tangible elements. Intangibles are frequently lumped in a single item because that may suffice for the purpose in hand, but for any refined valuation they should be segregated, and particularly so, when dealing with the specific inquiry of the value of a water right or any other single intangible. This lumping of intangibles tends to confusion, and not infrequently this lump sum is expressed wholly as a water-right value when that may not be the case at all. The intangibles may include "development costs", "going concern value", franchise value, water-right value, etc. The first two are things apart and rather definitely determinable. Franchise value and water-right value, however, may sometimes be confused, but each individual valuation case will usually afford some rational basis for segregation.

As applied to private industry, the logic of capitalizing excess net earnings as a basis for determining water-right values can hardly be questioned. It may also be correct as applied to a public utility, depending on the terms of the franchise under which the utility is operating, and, particularly, if the valuation case is one in which the rates and earnings of the property are found to be fairly definitely established, regardless of the method by which those rates may have been reached. This, in a sense, begs the question in respect to those public utility properties for which, in theory at least, the rates depend on the rate base rather than the reverse. For rate-making purposes, in such cases, a regulatory commission would have to use some independent method of arriving at the water-right value.

All these considerations and methods of determining water-right values may have application in certain cases yet none of them has universal application to the exclusion of the others. They may lead to quite different results and the one that should control depends on local conditions and on all the circumstances surrounding the particular case in hand. There is too much tendency on the part of appraisal engineers to adhere to rigid values in valuation work, some adopting that method which always yields a high valuation and others that which always makes for a low valuation. There are, of course, certain fundamental principles that must be observed, but an important

principle that deserves broader recognition than it usually receives, one that will tend to dispel the prejudicial view, is this: That no single method of valuation can be rigidly applied to all cases, that each case is a thing apart, and that the valuation method, to be applied, must depend on, and be adapted to, all the circumstances and conditions surrounding the particular case and business involved. Valuation work is complex at best, and to arrive at just results the appraisal engineer must possess, in addition to his technical knowledge, a discriminating fairness and an abundance of good judgment and common sense.

The author states that in building new irrigation works to replace old ones, the amount paid for those parts of the old works that were abandoned or destroyed, was, of necessity, added to the cost of the water or the water right. This, it seems, is properly a development cost and in no sense a proper charge against the water right. That it would add no value to the water right proper is evidenced by the fact that no one would pay this extra cost for the water right alone if, for instance, there was an abundance of water in the stream. This development cost would be reflected, of course, in the price placed on the stock of the company, but it would not, in the writer's judgment, represent water-right value.

The author also states that in his early appraisals it was deemed merely necessary to ascertain the prevailing sale value of water. When conditions are stable the market or sale price of water stock is at least a criterion of value that should be considered and in some cases it may be important. There are cases, however, where the market price of water stock is largely fictitious, bearing but little relationship to earning capacity or to actual investment. In such cases it would not be safe to deduce a water-right value from the market price of the water stock. The water-right value must, of course, be segregated from the all-inclusive stock value. At another point, the author himself recognizes the unreliability of this market price method of determining value.

The author's statement that stored water has little more value than unstored water requires some qualification. The truth of it depends much upon the flow characteristics of the stream involved. If the unstored or normal flowage water is exhausted during the very early months of the irrigation season, as it frequently is, then, even for identical volumes, the stored water would be more valuable to the crop than the normal flowage. In general, it is believed that stored water is more valuable, volume for volume, than unstored water, because it is under definite control, it can be delivered as, and when, required, and it is available in periods of the most acute need. The comparative values of like volumes of stored and unstored water, however, may be something quite different from the comparative values of a water right from normal flowage during the irrigation season and a water right for storage during the non-irrigation season. The exact definition of the water right and the stream characteristics are all important, because the average number of acre-feet of usable water that each water right will produce annually must be determined before a comparison of values can be made. The term "usable water" is empha-

sized because, not only does the right usually cease when beneficial use ceases, but a water right takes on value only as it has a dependable water supply, the equipment to deliver the water, and a market to absorb it. In water-power development, and also in domestic water supplies, the rate of stream discharge rather than the total volume of run-off may often be the more important consideration, so here, again, its adaptability to such a condition, makes stored water more valuable than unstored water.

Where there are several water rights on the same stream the priorities of those rights, and their time limitations within the year, if any, are important elements affecting value, and the length of the stream-flow record may also appreciably affect the water-right value. The writer agrees with the author that a longer record than eight years is desirable. A short-time record cannot develop true stream characteristics and a long-time record is likely to reveal worse low-water conditions than the shorter record would show. The effect of this would be to give greater relative value to the early priorities, and it may also give a greater value per unit volume of water. The length and dependability of the available discharge records are elements that should not be disregarded in water-right valuation work.

The author, in his development of water-right values for several specific cases of canal systems, does not indicate how the gross valuation of these properties was initially determined. He starts with an assumed, definite gross value, which is apparently the market value, and an assumed value for the physical elements of the property. Calling the difference between the gross value and the structural value, the value of the water rights, he develops a method of apportioning this latter value among the several water rights according to their priorities. The writer would first indicate that, since the water-right value results directly from the relative gross and structural values, the important primary consideration is the correctness of the method by which those latter values were determined. The author does not indicate what these methods were. This difference between gross and structural values is not necessarily the water-right value alone. It is the aggregate value of all the intangibles, and these may include elements other than water rights.

In the Fort Lyon Canal case it is stated that the gross value of the system is \$6 000 000, the structural value, \$2 000 000, and that the water-right value is, therefore, \$4 000 000 which, with an indebtedness of \$600 000, gives a total water-right value of \$4 600 000. It is not clear why the \$600 000 should be added to the water-right value. If it represents value at all it is presumably included in the gross value of \$6 000 000, and if it represents accrued operating losses that are in fact "development costs" they are not properly a water-right increment of value.

The author's method of segregating the total water-right value among the several rights on the basis of their priorities, is thought to be the logical and probably the only rational method for such segregation. It is believed, however, that in determining the quantity of water deliverable during the year under any decree, the possible yield for the full year should not be taken, but only the yield of that portion of the year during which the water can be put to beneficial use; as, for instance, during the irrigation season only. Unless

the decree specifically permits it, and there are facilities to deliver, and a market to absorb, the water deliverable during the non-irrigation season, the normal-flow water right for that period would have no value. Even storage rights for that season might have no value if the cost of the storage works should be greater than the value of the water stored. A recasting of the author's figures, on the basis of water yield during the irrigation season, will give an entirely different set of water-right values.

Determining the so-called efficiencies of the various decrees as bases for determining the value of a water right of 100% efficiency would seem to be an unnecessary elaboration because, after the value of the acre-foot of water is determined, one need only multiply that figure by 724 to obtain the theoretical value of a continuous flow of 1 sec.-ft. The word, theoretical, is used advisedly because no such 100% efficiency can obtain, regardless of the provisions of the decree, unless the water is continuously available and there exists facilities for its delivery and a market to absorb it in beneficial use. It is possible that, with storage and the development of markets, these conditions may sometimes be met, but without these essentials satisfied, such figures as the author develops for the value of water rights of 100% efficiency are academic and likely to be misleading.

FRED H. TIBBETTS,\* M. AM. SOC. C. E. (by letter).—To the present the engineer attempting to make a rational valuation of a water right finds little precedent and practically no authoritative literature to guide him. Mr. Field, accordingly, deserves all the abundant credit due for his important pioneer effort. The paper is of the greatest interest and value, containing a clear, concise, and logical method of fixing the valuation of a water right where the data required can be readily, and with certainty, procured.

At a time like the present, when agricultural securities are notably below par, and particularly in California, where State irrigation districts have issued more than \$100 000 000 worth of bonds, it would be of material assistance in financing additional developments if the general public, bankers, and Courts, could be educated to a proper recognition of the true value of reliable water rights available with certainty for irrigation development. It is the writer's hope that this paper will assist materially in creating recognized methods of fixing substantial values for water rights.

Mr. Field's method is to obtain the total value of a public utility, or mutual water company, furnishing water for irrigation, by determining the market price of its total outstanding stock and presumably other securities. From the value thus obtained he deducts the appraised value of the physical properties and assigns the remaining value, if any, to the water right. The few public utilities serving water in California, seldom have a total stock value equal to that of their appraised physical properties. Hence, although it is recognized that their water rights have substantial values, Mr. Field's method of obtaining such values is quite inapplicable. As a broad generalization, it seems highly conjectural to assume that all the stock value in excess of the reproduction costs (less depreciation) of physical properties, represents the

\* Civ. Engr., San Francisco, Calif.

value of the water right. This residual must also include the sum of all "intangible values", such as promotion and development expenses, organization, "going concern", etc. The total stock value of any corporation is also measurably dependent on public confidence in the officers of the company, and many times on the efficiency of its advertising. There are many corporations in which at times the total market value of the stock may bear but little relationship to the value of the physical properties. A good example, in California, is a certain boom oil company luridly advertised and over-capitalized, in which over-issued stock with no valuation whatever of physical properties back of it, may exceed \$50 000 000 to \$100 000 000.

The writer is somewhat of the opinion that Mr. Field's method attacks the problem from the wrong end. He is inclined to the belief that if he were to purchase a large amount of stock in the water companies which Mr. Field discusses, he would first appraise the physical properties and then, from independent considerations, would appraise the water rights, and, finally, from the total of these would determine what he considered to be the value of the stock. This procedure seems more logical than to accept public opinion regarding the market value of the stock as conclusive, and from this to assert that the difference between this market value and the value of the physical properties must represent the value of the water rights.

The writer is in fundamental disagreement with the author when he concludes that the value of an acre-foot of water is the same, whether it is used for domestic purposes, or for those of manufacturing and agriculture. It is certain that in California the cities can and do pay far more for domestic water than the farmer can pay for irrigation water. Mr. Field's statement that "except for the need of water for agriculture in the semi-arid region, there would be enough for domestic needs and for manufacturing", seems quite inapplicable to regions like Southern California, for example, where the duty of water per acre for urban development is about the same as for agricultural development, and where large quantities of water must be imported from far distant points to satisfy the domestic and industrial needs alone. The writer sees no reason why the value of water for domestic purposes should not be based on the city's necessities and on what the city can afford to pay; in particular, he sees no connection between the value of water for domestic and for agricultural purposes, and can discover no reason why the value for domestic purposes should be based on that for agricultural purposes.

Mr. Field suggests that the idea of converting the cubic feet per second, into acre-feet and basing the value of a water right on the number of acre-feet thus produced, at one time "appeared ridiculous". The writer is entirely in agreement with Mr. Field, however, in that this is probably the correct method. As a matter of fact, this is the only method for valuating a water right that the writer has ever used or considered. In determining the value of water rights for irrigation purposes the "useful yield" during the irrigation season should be determined in acre-feet, and the valuation based on this unit. The "efficiency" of a water right for irrigation purposes should then be the ratio between the number of useful acre-feet produced by this water right

during the irrigation season and the number of acre-feet during the irrigation season (included in the irrigation project's demand curve) which would have been produced by a second-foot flowing continuously during the peak demand of the irrigation project, and at other portions of the season reduced in proportion to the project's reduced demand.

While the author's method is logical and excellent for the conditions outlined, the writer believes that recent appraisals of water rights on the San Joaquin River, in California, were based on broader and more general principles.

The problem presented was unusually complex and complete, because nearly all conceivable elements of value were present in substantial quantity. The important water rights on a major stream controlled by a single private interest were proposed for transfer outright to a newly organized water storage district. As it was conceded that the district would not attempt to condemn the water rights, the problem was not complicated by intricate and archaic legal theory, as is so frequently the case. The appraisals described herein led to a final valuation of about \$9 500 000. This was a compromise figure agreed on by the writer, representing the owners of the water rights, and A. Kempkey, M. Am. Soc. C. E., Consulting Engineer for the District. The theories herein described are those developed jointly by Mr. Kempkey and the writer.

Chief consideration was given to the following elements:

- 1.—The market value as established or indicated by actual transfers of comparable rights under conditions similar to the one considered.

- 2.—The substitutional service value, or the cost of securing by some other method the same water supply as is obtainable by the appraised water right. Two other methods were readily available in whole or in part: (a) Impounding flood water; and (b) pumping ground-water.

- 3.—The water value, or the capitalized sales (per acre-foot), outside the District, of irrigation water at diversion points, under similar conditions.

- 4.—The land increment value, or, the net increase in value of the land to be irrigated, caused by the acquisition of a water supply for irrigation.

- 5.—The land decrement value, or the decrease in value of lands irrigated or partly irrigated under the appraised water right, arising from depriving them of their water right. This is an unusual condition, but it obtained in the proposed transfer, thus rounding out the problem. Water was to be taken from 178 000 acres of "grass lands" of inferior quality, irrigated for pasture, and transferred to new lands as yet unirrigated and arid, but of superior quality.

- 1.—*Market Value.*—It appears to be the general legal opinion that "market value" as shown by the sales of other water rights of a similar character under essentially analogous conditions, constitutes the true criterion for a valuation of a water right. Like most legal formulas, this opinion is theoretical and evasive. The "market value" of wheat may be thus determined. Water rights cannot be standardized; no two are alike; there are few *bona fide* sales in which the price paid for the water right can be clearly identified; and in the

last analysis final conclusions are subject entirely to matters of individual, professional, and expert opinion, as to the degree of comparability of the water right appraised with other water rights the market value of which has been estimated from purported sales.

It would also seem obvious that if there were sufficient sales to establish a "market" for water rights, then the value thus established must take into consideration all the usual elements of supply and demand in ordinary commercial transactions. In particular, it must be chiefly affected by the value of the water right to the purchaser, and its value to the seller. These two values must, in time, reflect chiefly the values determined by Elements 2 to 4, and particularly the last two, Elements 3 and 4.

Included in voluminous expert testimony in the Spring Valley Water Company rate cases in San Francisco, Calif., are deductions for the market value of irrigation water obtained by this method and varying from \$70 200 to \$1 272 per sec-ft. It will be obvious that the results obtained are entirely a matter of professional judgment as to the degree of comparability of the different water rights.

2.—*Substitutional Service Value.*—It is not always possible to obtain any substitutional service value because frequently no source of water supply can be obtained other than the one appraised. The writer believes, however, that much weight should be given to this matter whenever it can be clearly shown that there are one or more possible sources of water supply other than the one appraised. In many cases reservoir construction for the storage of flood water will furnish an entirely satisfactory, substitutional source of supply. Opinions may differ as to the relative value per acre-foot of irrigation water thus obtained. The writer believes that irrigation water obtained from a natural stream flow, the yield of which is known from long and reliable records, can be estimated more accurately, and hence, is more valuable, than a corresponding quantity of water which is merely the estimated yield from a storage reservoir not yet built. Mr. Kempkey, however, held that reservoir releases per acre-foot are more valuable than corresponding natural stream flow, because the construction of the reservoir allows, in the future, much greater elasticity of operation and variation in reservoir releases with variable seasonal weather, and variable crop production, over a long period of years.

Substitutional service in large part may also be obtained from wells, but here, again, the cost of obtaining a well supply, as yet unconstructed, cannot be estimated over a long period of years with any great confidence, because of the probable variation in pumping head and in cost of power.

3.—*Water Value.*—It is generally much easier to obtain reliable records of the sale of natural stream flow for irrigation ditch diversion, or of reservoir releases for irrigation purposes, than similar values of the sale of water rights. However, it may still be a matter of opinion as to the degree of comparability of the water sold, with that to be furnished under the right appraised. When reliable figures for the market value per acre-foot of irrigation water are thus obtained, they can be capitalized and used as a measure of the value of similar quantities of water to be obtained under the rights appraised.

4.—*Land Increment Value.*—Increase in the net value of irrigated over unirrigated land can usually be determined with considerable confidence, providing irrigation has been long practiced in the district under consideration. In obtaining the net increase in value of irrigated lands because of the irrigation water rights, the difference in value between the irrigated and the adjacent unirrigated land without water rights should be obtained, and from the difference thus obtained, must be taken the cost of improving the land, leveling it, checking it, constructing irrigation distribution, etc. Not all the net increase in value, as thus obtained, can be claimed for the water right; a portion should be claimed by the land and a portion by the agency which has provided and operated the physical works for the diversion and conveyance of the water.

In this connection it may be emphasized that at the instant the physical works for diversion and conveyance have been completed and the land owner has prepared his land for irrigation (with no water having been actually diverted), there does not exist a completed and valuable right in the sense that such a right will exist after many years of diversion and use. It may be assumed, therefore, with propriety that the water agency on the one hand and the consumer on the other, after years of operation, have contributed jointly (through diversion in one case and use in the other) to the creation of a property right having a very substantial value, to wit, a perfected water right. It will also appear that the contribution in each case has been independent of investment, and is based solely on the physical fact that the water agency, on the one hand, has diverted the water, and the consumer, on the other hand, has used it. Obviously, diversion by the water agency would be of no value without use by the consumer and in the case of the particular land in question, use could not have been effected without diversion by the public utility. It appeared, therefore, equitable that each should share equally in the property value thus jointly created.

5.—*Land Decrement Value.*—This method is clearly inapplicable, except as to lands that propose to give up their water right, resulting in their being dried up and rendered less productive. In the case considered, the value to the owner (of the dried-up lands and of the water right) was obtained by estimating the difference in value of the land, with and without the irrigation to which it had been accustomed, or by capitalizing the difference in revenue or rental from the same lands, with and without their accustomed water supply.

*Appraisal Units.*—To obtain a quantitative expression of the valuation of the different water rights the "safe net yield", in acre-feet, during the assumed irrigation season, was determined for each water right. The "safe net yield" was a term applied to the estimated minimum quantity of water allowable in the minimum or driest year. The normal water supply at the diversion points in the entire district of 554 300 acres was estimated at 2.45 acre-ft. per annum, with a monthly distribution as shown by Fig. 2 and Table 1. It was assumed that shortages in minimum years were allowable up to 33 1/3% of the normal supply. Fig. 2 shows the assumed water demand of the district.

A hydrograph, based on long years of record of the actual yield of the principal water right appraised, is superimposed. Under these conditions a theoretically perfect water right, that is perfect in monthly distribution, would yield 285.5 acre-ft. of useful water per sec.-ft. during the irrigation season.

TABLE 1.—AVERAGE ACTUAL YIELD OF THE WATER RIGHT.

Month.		January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.
District demand ....	Percentage per month..	0	0	6	12	21	29	17	13	9	2	0	0	100
	1 000 acre-ft. per month.	0	0	23.3	46.6	81.6	77.8	66.1	50.5	35.0	7.8	0	0	388.7
	Acre-feet per month per second-foot.....	0	0	17.1	34.3	60.9	57.1	48.5	37.1	25.7	5.7	0	0	285.5
Actual total..	1 000 acre-ft. per month.	14.9	15.0	29.0	50.1	77.8	79.0	77.0	49.5	27.8	22.5	16.5	15.6	474.7
	Acre-feet per month per second-foot.....	11.0	11.0	21.8	36.8	57.1	58.0	56.6	36.4	20.4	16.5	12.1	11.5	348.7
	1 000 acre-ft. per month.	0	0	23.3	46.6	77.8	77.8	66.1	49.5	27.8	7.8	0	0	376.7
Yield useful..	Acre-feet per month per second-foot.....	0	0	17.1	34.3	57.1	57.1	48.5	36.4	30.4	5.7	0	0	276.6
	1 000 acre-ft. per month.	0	0	23.3	46.6	77.8	77.8	66.1	49.5	27.8	7.8	0	0	376.7

The relative values of different water rights appraised were determined by superimposing on the hydrograph of the water right, as obtained by measurements over a period of years, the irrigation demand curve of the district, and their relative value was determined to be strictly in proportion to the number of acre-feet which each right would produce within the demand curve of the district.

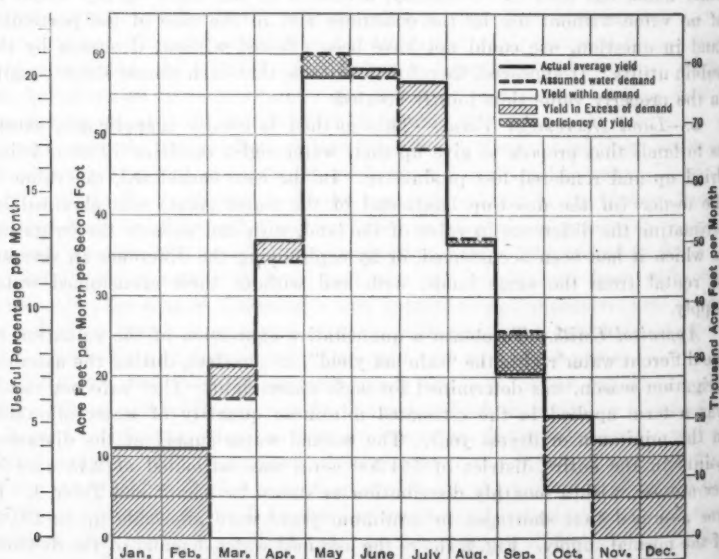

FIG. 2.—AVERAGE ACTUAL YIELD OF THE WATER RIGHT.

The final conclusion was that water rights from the San Joaquin River, for acquisition by the San Joaquin River Water Storage District, delivered at the head of the distribution canals, were worth \$30.40 per acre to be irrigated with a normal demand of 2.45 acre-ft. per acre, or were worth \$18.58 per acre-ft. of "safe net yield" obtainable during the minimum year of record.

CHARLES R. HEDKE,\* M. A. M. Soc. C. E. (by letter).—In the early stages of Western irrigation developments water was clearly provided to supply a local need in agricultural products for the margin between the cost of production and returns therefrom, at that time. It was simply a case of values then possible between demand and supply. The resultant of those two general forces constitutes the same basis now and will hold the forces making all future water values. Formerly, this basis of valuation was not affected by the many factors now involved but with the great growth and expansion of the country and its agricultural industry it can be readily seen that water values now are not such a simple matter. They have become quite complex. It is suspected that every hydraulic engineer has come sternly face to face with naked water values and has been disappointed in his search for information, so the courage of Mr. Field in opening the large subject should not go unmentioned.

Water is one of the natural resources of the country. It is indispensable for plant and animal life. Under the energy from the power station in the sun it forms the transportation system of all plants. It is continually moving, through evaporation and precipitation, and those phenomena constitute the fundamental water cycle in Nature where they are equal and opposite in direction. There is no permanent loss of water anywhere and Nature has provided its purpose and use. Like in all other natural resources, Man is undertaking to obtain from water its maximum use and value. In its extended use additional values are created, as certainly as for the soil or the minerals. As soon as the first additional value is made ownership will attach. Public ownership is natural and essential in the outset for water, just as it was for land, but there is no more reason why water should forever remain the property of the public than it is for the land or the minerals to be common property forever. No section of this country has escaped the inevitable result, yet Colorado is the only State which has shown the courage to clearly recognize it and openly declare water subject to private ownership. It is natural, therefore, that Mr. Field, a former State Engineer for Colorado, should complacently open the unsettled subject without ever mentioning ownership. A peculiar situation thus presents itself.

Within the general plan of Nature, it appears that two fundamental natural resources are necessary for the production of crops—climate and soil—and they have been properly related in Nature for the production of each particular crop. The understanding of the proper correlation of all the factors in this combination constitutes the science of agriculture. This is perhaps the oldest science, but it still appears that Man knows very little about it. Present knowledge places temperatures and rainfall as the most important

\* Cons. Engr., San Antonio, Tex.

factors in climate and holds that these fix the natural locations for the growth of each crop. Thus it is that wheat, corn, cotton, rice, cane, or apples, peaches, oranges, bananas, or strawberries, blackberries, coffee-berries, or the various nuts, vegetables, oils, drugs, and woods appear with a distinct zone for their natural and economical production.

Under irrigation there is obtained the control of moisture for the growing of plants, and similar soils are found in each temperature zone, and yet crops are limited under irrigation; so it must be concluded that temperatures, which measure the heat energy available, are the controlling factor in Nature's crop zoning. Apparently some crops require a large amount of heat energy for their growth; others are suited for less heat; some want it between certain low limits, others between higher limits, and still others between extremely high limits and can stand no low limit at all. Such limitations appear to fix their production areas, provided the other factors of water and soil are suitable.

The writer believes that a definite and fixed general relation exists between the heat energy required for reproduction of a crop and the water requirements for that crop. It is further indicated in Nature that the same amount of heat energy requires the same amount of moisture supply in all plant production. Under that theory it would take the same amount of heat energy and water supply to produce a crop of oats in Texas, Colorado, or Alaska, all other factors except time being equal. The water requirements between crops then depend on their heat requirements. Large heat requirement crops will need large water requirements. High heat requirement crops may not necessarily need large water requirements. The essential factor seems to lie in the initial growing point for the plant as that appears to fix the point in Nature's energy supply which is required to start growth and place it in the zone of temperatures necessary for maturity and reproduction. All this is mentioned here to show that in the last analysis the value of water will lie in each particular kind of crop and the time required for its production to demand value. An acre-foot of water, in the Colorado River Basin, used in Central Park, Colorado, for the growing of native hay, field peas, or perhaps potatoes, all low and short heat requirement crops, will have a certain value, but if that acre-foot were used in the Imperial Valley, for the production of early lettuce, celery, potatoes, or citrus fruits, it would have quite another value, on account of the difference in time and kind of production.

The method proposed by Mr. Field for the evaluation of water rights does not go far enough. It is too local, because he bases it entirely on the \$6 000 000 estimate given as the value of the Fort Lyon Canal property, but does not show how or why it should be that amount. It is the basic figure which is important and how that was determined, which is essential in the problem; also just how and when that value was created, would be of interest. Furthermore, in the computation used for volume delivered, an average quantity value is obtained, but is not made the final basis of value as the delivery did not cover the full year, and so a correction was made therefor. In that section it is believed water is not used for irrigation during the entire year, so there is no right attached for a full year's diversion and storage rights probably intervene to cover that unused period. It does not appear sound to

extend values on that basis and the first value figure obtained by the author stands on a firmer basis than the later one.

It may be of interest to follow the economic steps necessary to create a real water value from its extended use by irrigation. The owners of land, in every semi-arid section of the West, with possibilities of obtaining a supplemental supply of water from a stream, in order to assure full and certain production, have thought, talked, and even taken what action they could, for some step to attach the possibility of a right to the use of some water to their land. A single owner of land soon discovered that he alone could rarely undertake such a task and hence with his neighbors, in mutual organization, the early developments were made. This form of development imposed heroic struggles and has since been supplanted by better means. The history of changes made in the developments by irrigation have been ably recorded and do not need to be repeated here. However, from the very beginning, the use of the water has been made the basis for a value and its contemplated use made a potential security aspect of considerable importance.

At the outset, for all irrigation properties, the valuation of the water can only be justified on the basis of the cost of the development. Unfortunately, the potential value of water was seen, grasped, and capitalized by speculators, who added it to the land values, and from that practice has grown the troubles from most land settlements under irrigation properties. The real value of water is created by its use and is represented by the actual production of crops the value of which is sufficient to show an attractive margin over the cost of production or over the returns from other competing areas growing similar crops. It does not come into existence until tried and proven use has been made and so should accrue to the party whose work and effort created that value. Any other basis is economically unsound and it appears the other viewpoints have led to much of the present irrigation trouble. Leave the possibility of a reasonable value of the water to accrue to the settler of the land under irrigation, who must make the value, and a changed aspect on most irrigation developments will be noted.

The kind of crops grown and the time of their possible production forecast the basis for the fundamental difference in the value of an acre-foot of water for irrigation purposes. Any crop grown, on the short-season areas, will come on the market after all other areas of longer season have matured similar crops. For staple crops that handicap may not be so serious. What is perhaps now more depreciating is that such short-season areas are sharply limited in the kind of crop grown so that the areas above them, in the scale of thermal location, contain less hazards and more advantages, which give the latter a better competitive position and thus reduce the value of water in the lower scale area. The oversight of such forces might be pointed to for some of the difficulties inherited by the present Reclamation Bureau. Its recognition then might furnish the basis for a defensible adjustment in their properties, between which relative water values could be determined and these values credited to the user by deduction from the construction cost, when apparently the water value was permitted to be attached. There is little possibility of finding a water value in some properties, with costs of construction

and locations known to all irrigation engineers; and this does not mean all Government projects, either.

For some time, the writer has had a growing conviction that the most essential feature in the feasibility of an irrigation development lies in the condition that a clear water value can be reserved for the settler, as compensation and his margin; for the courage, self-denial, effort, and time it will take him to create the value of water for irrigation purposes. If a standard for such a margin could be agreed upon as just in all developments it would soon be quite clear in which zone of thermal location the irrigation developments in the near future would be undertaken.

In the same temperature locations, and under similar crop production, the several areas have a varying demand for water due to the difference of the natural water supply furnished by rainfall. The Imperial Valley of California and South Texas have a very close thermal position and their crops will be much the same; yet with the same consumptive use of water by cropping, which, for illustration, is taken as 36 in. applied to the land, the Imperial Valley obtains little if any direct water supply from rainfall, while South Texas will average (in the effective support) about 15 in., from its rainfall supply. In one case 3 acre-ft. of water are required to produce the crops, whereas in the other case, 1.75 acre-ft. will produce the same results.

From such practical conditions, which vary for every section, it would seem that a differing value of water exists for each section, and that it does not even remain stationary, but will rise and fall as the margins in the crops produced fluctuate.

FRED C. SCOBEE,\* M. AM. SOC. C. E.—In his discussion of the value of reservoir rights the author does not make a distinction that appears essential. A great difference in the right to obtain water from a reservoir lies in the terms of the contract. Does the right entitle the holder to certain space in the reservoir or does it entitle him to definite quantities of water from the reservoir? In California and elsewhere, a number of contracts have been made in recent years whereby one organization agreed to pay to another a certain amount per acre-foot for water delivered—not space in the reservoir but tangible water.

On the other hand a favorite form of agreement entered into several years ago, particularly in Colorado, entitled the purchaser to a certain number of acre-feet of space in the reservoir. If full storage was obtained in any one year the presumption was that water to the extent of the right was started flowing from the reservoir to the lands of the purchaser, who stood the conveyance losses en route. If full storage was not obtained in any year the available water was pro-rated. The space in one well-known reservoir on the South Platte River was sold on the basis of a capacity of about 85 000 acre-ft. As constructed, and as further limited by action of the State Engineer, the reservoir has never had an available capacity of more than about 30 000 acre-ft. Here, the available capacity was only about one-third the assumed paper rights. In "short" years this is, of course, further reduced. Finally, what appeared

\* Senior Irrig. Engr., U. S. Dept. of Agriculture, Berkeley, Calif.

to be a good and sufficient water right dwindled to merely a supplementary right.

Another case is that of an organization in Utah that sold to another some space at the top of its reservoir. Moreover, it was a space that had seldom or never been filled. In cases like this the numerical volumes of prospective water may be such that a right looks good and sufficient to a land settler, and he does not find that space and water are not synonymous until he fails to receive the latter. When evaluated a distinction must be made.

There are, of course, many reservoirs that receive a full supply practically every year. For these, the consumer's rights need not be discounted. However, there are also reservoirs for which rights have been sold, that are worth only a small part of the same right if it could obtain the water numerically described therein.

LYMAN E. BISHOP,\* M. A. M. Soc. C. E.—Water rights in the Antero Reservoir near Denver, Colo., entitle the holder to a *pro rata* share of the quantity of water stored each year. The farmers under the Highline Canal own and control 11 254.6 acre-ft. of storage capacity rights in Antero Reservoir. These rights were sold to the farmers by the Antero and Lost Park Reservoir Company and were outstanding when the City of Denver purchased Antero Reservoir and the unsold water rights in it.

The Antero Reservoir water rights of the Highline Canal farmers were in litigation for several years. The Colorado Supreme Court in its decision, interpreting and deciding the value of these outstanding rights to the holders, stated in part:

Farmers have "right to share upon a *pro rata* basis in the capacity of the reservoir in acre-feet as such capacity becomes available \* \* \*.

"\* \* \* a right to use such proportional part of the water as might be stored with an agreement \* \* \* to use reasonable diligence in filling \* \* \*. \* \* the contract nowhere provides that they are to receive an acre-foot of water per acre each year out of the reservoir.

"\* \* \* the rights of the farmers under their contracts can be no more than the right to use, on a *pro rata* basis, whatever water may be stored in the reservoir".

It should be noted that the Court states "water as might be stored" and "whatever water may be stored" and does not state or use the terms "is stored" or "is in storage" at any time or year. The City of Denver and the farmers are each entitled to their share and undisputed use, enjoyment, and ownership of their respective capacities. Each may use his stored water; each is entitled to his *pro rata* share of the water that "may be stored" at any time; each can accumulate and hold over his storage; and unless (or until) all the capacity that belongs to either is filled with water, there has certainly been no damage done to the other. Most assuredly, under Colorado irrigation laws, neither the city nor the farmers will be penalized for conserving water in storage any year and then be required the next year to *pro rata* or divide what has been saved with the other who has used his previous year's storage supply.

\* Cons. Engr., Soviet Union Middle Asia Water Economy Service, Care, Sredazvodhoz, Tashkent, Soviet Turkestan, Union of Socialist Republics.

The Antero Reservoir as constructed had a capacity of 58 601 acre-ft. At present (1928), on account of the weakened condition of the dam, concrete facing, etc., the State Engineer has limited storage to 33 276 acre-ft. Therefore, the "Highline farmers" who own water rights in this reservoir now control

$$\frac{11\,254.6}{33\,276.0} = 33.82\%$$

of the total water stored in Antero Reservoir each year and

the City of Denver owns

$$\frac{22\,021.4}{33\,276.0} = 66.18\%$$

per cent.

The reservoir was completed in 1909 and water was first stored in May of that year. The City of Denver owns 47 346 acre-ft. and the farmers own 11 255 acre-ft. of Antero Reservoir's original constructed capacity. The reservoir has a decree of date, October 8, 1907, in the amount of 85 564 acre-ft. Of this decreed capacity, the farmers own 11 255 acre-ft. and the City of Denver owns 74 309 acre-ft. Irrespective of its usable capacity, the farmers under the Highline Canal holding Antero water rights own the full amount of 11 254.6 acre-ft. of storage capacity rights. If the reservoir were restored to its original constructed capacity of 58 601 acre-ft., the City of Denver would then own 47 346 acre-ft. of storage capacity rights instead of the 22 021 acre-ft. now controlled; and if the dam were raised to provide for an additional 6 ft. in depth of storage above the present constructed full supply level, the city would then own and control 74 309 acre-ft. of the then constructed and decreed capacity of 85 564 acre-ft. The date and the amount of the decree that has been entered for Antero Reservoir (October 8, 1907, and 85 564 acre-ft.) are of considerable importance. The storage decrees for Barr Lake enlargement, Prospect Reservoir, Horse Creek Reservoir, and Milton Lake are all of later date than the decree that has been entered for Antero Reservoir. This is quite significant because, since this decree is already entered and is a final one, the raising of Antero Dam to permit the storing of the decreed capacity of 85 564 acre-ft. would result in placing the demands for Antero storage ahead of the demands of Barr, Milton, etc. The South Platte River is the source of water supply for all these reservoirs.

Under the joint ownership and operation by the City of Denver of Antero Reservoir and Lake Cheesman the possible storage available for Antero Reservoir has been estimated in detail by the speaker for each month of the years 1900 to 1925, inclusive. This estimate of possible storage reveals the following as available annually for Antero Reservoir:

Mean (26 years).....	20 515 acre-ft.
Maximum (1914).....	58 601 acre-ft.
Minimum (1908).....	3 845 acre-ft.

The records of Antero actual annual storage since 1909, show the following:

Mean (19 years).....	13 214 acre-ft.
Maximum (1918).....	27 801 acre-ft.
Minimum (1911).....	3 842 acre-ft.

From the foregoing brief statements it will be realized that the value and probable yield of Antero water rights are subject to several criteria. The

usable capacity of the reservoir; the variation of the available gross storage; and the requirements and use of the stored water by the water-right owners, are the three principal arguments. All these considerations are subject to change and all changing results in variable yields for Antero water rights and correspondingly different values.

R. L. PARSHALL,\* Assoc. M. Am. Soc. C. E.—If there is some basis on which it could be said that a second-foot of water has a particular, definite, fixed value and that there is some relation existing between the value of a direct flowage right and storage right, it may be of interest to know that approximately 3 000 acre-ft. of stored water in the Arkansas Valley, in Colorado, was recently purchased at \$2 per acre-ft. In the northern part of the State, near Fort Collins, the value of stored water varies according to supply and demand. As a minimum, water in storage sells from \$40 to \$60 per 1 000 000 cu. ft., while, at other times, the price is as much as \$200. In June, 1927, stored water was sold for about \$95 per 1 000 000 cu. ft., which is, roughly, \$4 per acre-ft.

S. H. STIVERS,† M. Am. Soc. C. E. (by letter).—For some time past, the valuation of water rights has been the subject of extensive investigation and study, as well as of judicial review. This subject is of increasing importance as shown by the widely divergent views and decisions, in recent rate cases, and the present tendency of legislative bodies in the enactment of statutes affecting rates, earnings, consolidation, and mergers.

The writer's understanding of Mr. Field's method of valuation is that he first determines the total market value of the outstanding stock and other obligations. From the result so determined, he deducts the appraised value of the physical property and plant, the residue plus certain indebtedness being assigned as the value of the water right. Without raising any question as to the reasonableness of that value in this particular case, it is apparent that the method of determination is contrary to the generally accepted methods of valuation. It is, therefore, fundamentally unsound inasmuch as its validity is at least problematic in view of the decisions of the Courts in recent cases, and relates itself to the fundamental principles of valuation thus far announced by the Courts.

At one time valuation was defined as a determination, by competent public authority in the exercise of a governmental function, of a sum representing the total property invested in an enterprise. This sum, however, would not necessarily represent or indicate the relationship between the sum thus found and the property itself.

Rate-making is the most fundamental purpose of valuation, because it determines the earnings of the enterprise; and these earnings, when determined and fixed, will establish to a large extent the commercial value of that enterprise. The consideration of the basis of a valuation for rate-making purposes involves the fundamental principles of economics, political science, and law. The method must be sound from the economic point of view, or it will result

\* Irrig. Engr., U. S. Dept. of Agriculture, Fort Collins, Colo.

† Cons. Engr., Washington, D. C.

in hardships and confusion. It must be correct from the point of view of political science and National policy, or great injustice may result to the utilities, to its patrons, and to that part of the public that has invested in its securities. It must be judicially sound, or constitutional legal rights may be usurped and the whole proceeding may be invalidated, because the power of judicial review over such valuation has become firmly established in American constitutional law. A valuation based on political expediency, however, is to be deplored from a scientific point of view and will inevitably result in a change in the National policy in the event that such a valuation receives the approval of the highest authority.

It is apparent that theory as to correct "value" ranges from that of the economist, which is market value or exchange value, to the theory involving original cost of the enterprise and to the so-called prudent investment. It is submitted, however, that the judicial concept, in so far as it has been developed, is not strictly "value", and that judicial dicta, if not judicial decisions, might be construed to support almost any one of the theories that might be adopted. It will facilitate comparison of these theories to analyze the fundamental economic principles to which they apply and to which they give varying considerations and weight.

*Market Value.*—This theory runs through valuation literature from the discussions of the Georgia Commission, in 1880, to the present time (1928), and purports to be the economist's true concept of value. By no process of reasoning, can value in exchange be found in advance; it can only occur in the event of a sale, and if there is no sale, there is no value in exchange. An attempt to determine this value in exchange is merely an effort to estimate what such a value would or might be if a sale takes place. In the case of large utilities the so-called "market value" is rarely ever determined, because such properties are rarely subject to purchase and sale.

The market value of stocks and bonds does not necessarily indicate, with any degree of accuracy, what the sale value of the plant would be. The stock and bond quotations on the market are generally the result of offers to sell and bids to buy such securities as are offered for sale, and this floating supply usually represents only a small proportion of the total outstanding. A steady and consistent demand and a diminishing supply of the securities might indicate negotiations for control of the enterprise, and such control might be desired, or required, for reasons entirely foreign to the value of the property. On the other hand, if a large part of the outstanding issues was thrown on the market, the inability of the market to absorb them might result in a substantial decrease in the prices quoted or bid; and if bids were made for substantially large blocks of stock without a corresponding release on the part of present holders, quotations would be affected by purchases for speculative purposes, without regard to the value of the property represented by the securities. About the most favorable claim that can be made for this theory of value is that if the market is in exact equilibrium (an almost impossible hypothesis) the quotations represent the judgment of investors, or speculators, as to what the earnings and the probable speculative value of the securities might be. The value of shares in mutual irrigation companies may represent, in some

instances, the fair value of the property because this value sometimes represents the amount the farmer is willing to pay for a certain quantity of water delivered at the point of use.

The correlative theory sometimes suggested for rate-making purposes is that capitalized earnings represent value. These earnings are a sum representing the value of the utility to its present owners, and, while this factor may have a decided bearing on exchange value, it is not exchange value itself. This rule must inevitably disrupt the question of reasonable profits, since it involves the so-called vicious circle that the reasonableness of rates depends on the value of the plant operating under reasonable rates.

*Original Cost.*—Many theorists hold to the actual investment theory of value. If it is assumed that money was invested, they claim that the actual money outlay is the basis of value; but investment is not necessarily limited to this narrow meaning. It can be interpreted as investment in property or investment in purchasing power. This is necessarily true and derives its significance from the general changes in price level. If such changes had not occurred, there would have been little or no necessity for any theory of valuation, because investment in terms of money would have satisfied both the legal and the economic requirements. The primary objection to considering investment in terms of money alone, is that it excludes artificially the rate base of utilities, railroads, etc., that are subject to statutory regulation, from the operation of economic laws, which are controlling in the case of all other classes of business. If rates are based on investment in terms of money and the price level changes upward, regulatory rates would become out of line with other prices, and the public would enjoy a purely artificial advantage, due to the accidental circumstance that the plant was built at a time of low costs. Patrons then will continue to pay rates that are unreasonably low as compared with prices in other classes of business in which they themselves are engaged. It has been repeatedly held by high judicial authorities that utilities subject to statutory rate regulation are entitled to share in the general increase of property values, and this rule seems to be less arbitrary and more economically sound than to adhere slavishly to the rule that investment in terms of money is the proper basis.

Such a rule is equitable, because, if the price level declines (even if the dollars received from the enterprise will be less than if rates were based on the investment in terms of money), this will be compensated by an increase in the purchasing power of those dollars in terms of other commodities. Money is used as a standard of value purely for convenience, and as a standard of deferred payments it is generally recognized by economists to be faulty. However, it is probably better than any other standard that might be adopted. Assuming that utility investment should be stable, it is no more certain that this stability should be in terms of dollars than in terms of purchasing power.

While investment in terms of purchasing power would probably be theoretically more correct than investment in terms of property, it would be difficult to ascertain and apply. The latter method will give nearly the same results as the former and it offers an easier means of determining cost of reproduction at present unit prices. Approaching the cost of reproduction basis from the invest-

ment angle, through the idea of investment in terms of property, its merit, namely, that it recognizes change in price levels, is retained, while the arbitrary and speculative features of the method are eliminated.

No hard and fast rule, or formula, can be laid down to govern the valuation of water rights, or of any plant or industry. The appraiser must determine all relevant facts that have a bearing on the value and give due consideration to all of them. This rule was first handed down by the U. S. Supreme Court in the case of *Smyth v. Ames*. This now famous decision enumerates the items of evidence to be considered in finding the value, but carefully avoids laying down any formula for applying them to the results sought. The Court simply states that all these factors must be considered, and then there must be a reasonable judgment based on a consideration of all relevant facts. The Minnesota Rate Case quotes this dictum with approval.

*Water Rights Must Be Valued.*—The question often arises, "Should water rights be valued"? It is clearly settled by numerous decisions to the effect that when water rights have been reduced to private ownership, either by appropriation, or purchase, such rights must be valued, as in the case of any other privately owned property. (See *San Joaquin Co. v. Stanislaus County*, 233 U. S., 454; *Spring Valley Water Co. v. San Francisco*, 192 Fed., 137.) A water right is private property and in a rate case the owner is entitled to have the value of such right included in the rate base. However, a distinction should be made between water rights that have been reduced to private ownership and contract rights for water. The U. S. Supreme Court, in the *Indianapolis water case*, includes the value of water rights in the total valuation.

*Quantity of Water to Be Valued.*—This will vary in different States, because of the statutory provisions of the State laws. Some provide that, to reduce appropriated water rights to private ownership, the water must be put to beneficial use; only so much as is put to such use, becomes the property of the appropriator, provided, of course, that this beneficial use is not limited by, or in conflict with, prior appropriations from the same source of supply.

*A Part of Land Value.*—If the water rights are incidental to the ownership of the land, or appurtenant thereto, they should be valued as a part of the land itself. (See *Portland R. E. & P. Co. v. P. U. R.*, 1916 D, 876, 1022.) Such rights may be classified as follows:

- (1) Those in which the source of water is on the land, and is controlled by the ownership in the land, such as percolating waters, springs from which water does not flow, or storm waters impounded in reservoirs.
- (2) Those in which the source of water is on other land, but the right to use it has been attached to owned land.

It will be observed that, in the first case, the water right inheres in the land as a matter of law, and in the second case, as an easement on a servient tenement. If the land were sold, the water right would pass with the land unless reserved in the grant, as in the case of reservoir land and storm water. It is the writer's opinion that water rights of this nature should be valued as a part of the land. This condition may vary in the different States, due to State laws.

The question does not arise with respect to rights of appropriation, because ownership of land is not necessary in order to acquire and retain a right of appropriation. Such rights have a value separate and distinct from the value of any land.

Commissioner Loveland, in his opinion (Santa Cruz, P. U. P. 1915, F. 768, page 792), states:

"\* \* \* This is a case of the appropriation of water from the banks of a natural stream by an appropriator, who did not own land in connection with such appropriation. The evidence in this proceeding shows: First, there is a live stream; second, the doctrine of riparian rights and appropriations can be applied in this case; third, the water company is not the owner of land in connection with such diversion of water. I am of the opinion that the water rights have a value separate and distinct from the lands.

"\* \* \* after considering these different elements of value, I recommend that some such sum be allowed as these water rights must have cost if purchased to-day."

*Value at the Source.*—The writer is of the opinion that a water right should be valued at the source of supply. The water itself may be diverted from the original source and may be led for long distances through ditches or pipe lines and put to beneficial use at some other point. Nevertheless, it appears equitable that the proper value is the value at the source and not that at the point of use. This is well sustained by the Courts for (in Spring Valley Water Company v. San Francisco, 252 Fed., 979, 984 (1918)), the Court has stated:

"\* \* \* Under such circumstances to allow the company the full value of water-shed and storage reservoirs and add thereto the value of the water when collected and stored is to place a double burden on the rate payers. The plaintiff is undoubtedly entitled to the full value of its storage facilities, but, in addition thereto, it is only entitled to the fair value of the water rights in their natural state \* \* \*"

*Elements of Value to Be Considered.—Cost.*—Some of the State commissions seem to be unduly influenced by the theory that, originally, the States permitted rights of appropriation to be freely acquired. They conclude that it is not in the public interest to permit these water rights to be valued, in rate-making cases, at a sum in excess of their cost, regardless of the fact that the right in question may have a value entirely different in exchange or in condemnation proceedings. It is presumed that this is predicated on the theory held by some commissions, that only actual cost to the utility can be assigned to franchise rights. The writer is unable, however, to identify a water right reduced to private ownership, with a franchise right, even though such ownership rests in a public utility under governmental regulations.

In its first decision involving the value of a water right, or water power right, the California Commission held that if the appropriation was made for a public use (apparently public utility use), it was held in trust for the public, and that the gift or donation by the public could not be capitalized against it. On the other hand, if the appropriation was made for private use and later acquired by the public utility, it should be valued at its cost to the utility. (See Northern California Power Co., 1 Cal., R. C. D. 315.) After the decision of the Supreme Court in the San Joaquin case, that body frequently took

occasion to deplore that holding (see *San José v. San José Water Co.*, 4 Cal. R. C. D. 1101; *re City of San Diego*, 4 Cal., R. C. D. 902; *re City of Glendale*, 4 Cal., R. C. D. 1011, 1019), as in the Glendale case, it is stated that a commissioner should make such a finding as he believes to be fair, "always limited by what he thinks higher authority will permit, which higher authority in many instances, we are led to believe, does not give the conscientious thought to this subject which it should." In some of its subsequent cases, while the written opinion was orthodox, it is impossible to determine what sum was included in the valuation of the whole property for the water rights. Appraisers cannot, however, escape the decision of the Supreme Court (*San Joaquin case*) that the cost of the right is immaterial, and that the Supreme Court of Idaho held (see *Murray v. P. U. C.*) that the cost may be considered, but is not conclusive as to value.

It may even be admitted that if the water right were valued at, or near, the date of its acquisition, the cost might be an indication of its value. If the cost of the right was small, its value was probably small, even though its utility and potential future value was high. Subsequent thereto, changes have usually occurred to such an extent as to alter completely conditions surrounding the right. Furthermore, there is generally a quasi-monopoly feature in water rights as well as in land, since the supply is usually limited and the demand in a developing community is increasing. The utility of the right for particular purposes may have greatly increased; its irrigation utility may have become higher, due to improved market conditions for crops, changes in the art of cultivation, and the development of new crops, thereby making it more profitable to irrigate, and increasing the amount the farmer can afford to pay for water. Additional or different utilities for the use of the water may have developed. All these changes enter into the new value of the water right and preclude the possibility of using the cost as value. Moreover, the owner (whether an individual or a public utility) is entitled to the increased increment of value. It can scarcely be said that there is any more reason for confiscating this increment in the value of water rights which have accrued in private ownership, than for confiscating the increment in land value.

*Next Available Source.*—A method advanced by some authorities is the use of the capitalized savings over the cost of bringing water from the next available source. This can only be based on the assumption that the right is worth what it would cost to bring water from the next available source and convert it to the same use to which the water right under consideration is devoted. This assumption seems contrary to fact, and its effect might be to pyramid the strategic value of the right in use, a result which is indefensible under the decisions heretofore discussed (*Spring Valley Water Co.*, *supra*).

Even conceding that the water must be brought from the next available source, this method is purely relative and gives little or no consideration to the utility of the right being valued, being concerned only with its relative utility in terms of the utility of another right. The value of the second right can only be measured, by this method, in terms of the value of a third right, and so on, *ad infinitum*. If this theory has any merit at all, it can be extended

to produce a value, determined by the savings over the most expensive source, rather than over the least expensive. This method appears in conflict with a Court decision on this subject.

In the case of *Brunswick v. Maine Water Co.* (99 Me., 371), it was sought to condemn the property of the Water Company, including its water rights, and the Court said:

"\* \* \* A water company undertaking to supply a community with water is bound to do so wisely and economically. It is bound to take advantage of practically natural facilities. If there is more than one source of supply, other things being equal, the community is entitled to have the least expensive one used. \* \* \* For instance, if water can profitably be served from a nearer source of supply, the Company ought not to be permitted to charge a higher rate based upon the expense of bringing it from a farther and more expensive source."

Furthermore, this method, being purely relative, can be reversed and the water right, not being appraised, can conceivably be given a negative value when compared with zero for the right being valued. Having adopted this comparative method, the question is, which of the two sources shall be taken as the standard, the one which the utility would use in the exercise of ordinary business judgment, or the one which it might use if it were imprudent enough to do otherwise. In the absence of an elaborate survey of all visible and underground resources there is no definite assurance that the assumed supply is, in fact, the next available source; and if all this assumption were definitely assured, the theory is still invalidated by the necessity of valuing the right at its source and in its natural state.

*Substitute Plant Theory.*—A somewhat similar basis sometimes adopted is the saving in the cost of operating by water as compared with coal or oil in valuing water-power rights. This covers more ground than the "next available source" method, in that it resorts to a substitutional means of manufacturing electrical energy. Some decisions can be found that favor this as a measure of value, while others disapprove it for the following reasons: It is comparative only; it is unstable in that its value is reflected in the changing prices of the fuel; and it deprives the public of all benefit from a natural resource to which they are adjacent. Some commissions hold that this saving should be shared with the consuming public, while one of the principal arguments against it is found in the decisions that it results in the maximum possible value and that it ignores the all-important element of supply and demand.

*Market Value the Test.*—Practical economics, as well as a long line of Court decisions, appear to demand that the market value of a water right is the true test. That is, it is the true market value determined from a consideration of all relevant facts in view of all their available uses and all the circumstances affecting their value.

It is important to distinguish between the market value of the right and its utility, or usefulness, to the owner or user. Market value may be denominated as value in exchange and can be said to be determined by the varying utilities to possible purchasers and affected by the doctrine of supply and demand. A common example of the distinction between value and utility, is the air. Its utility is inestimable, since no life can exist without it, while its

value is nothing, since there is more than enough air for all who require it. Another example is water; in most Eastern States, where the supply is greatly in excess of the demand, it is of practically no value, but its utility is great.

A water right has a utility to sustain life, another utility for domestic use, another for railroad purposes, another for irrigation purposes, another for developing electrical energy, and another for stock raising. These utilities vary considerably in value, and represent what it is worth to users of water for the purposes indicated. The utility seems to be a logical starting point in any computation of value which may be said to be a ratio between supply and demand, operating on the highest utility represented by the market. It is recognized, of course, that the adaptability of a water right for various uses is a necessary element in the determination of market value, but its adaptability for any one particular purpose, or its usefulness for that purpose, does not necessarily govern its market value. In condemnation cases, it is a clearly established rule that the object of the inquiry is the market value of the property taken, in view of all its available uses, and not its usefulness to its present owner, to the taker, or to any other person.

The market value of water rights will vary widely in different sections of the country, because in sections of normal rainfall such rights have little or no commercial value for ordinary purposes, while in arid or desert sections almost any water right has a very decided value. The writer had occasion to undertake the valuation of a water right in the arid or semi-arid sections of New Mexico, and gives herewith the salient factors used in the determination of its value. This is not put forward in any sense as a criterion of a universal method, but is submitted as one method of valuing a water right of this character.

*Description.*—This water right is owned by the El Paso and Southwestern Railroad Company, which extends from Santa Rosa, N. Mex., in a general southwesterly direction, through El Paso, Tex. The line is located along the eastern slope of a spur of the Rocky Mountains and traverses both a high rolling and extensive flat arid area, or *mesa*.

This vast desert area, almost barren of vegetation, except for the usual desert mesquite growth, is practically without natural drainage, with the exception of small streams which originate on the slopes of the surrounding mountain ranges during the short periods of rainfall and snow melting. From Santa Rosa westward, the railroad is constructed on the desert uplift, until the Corona Divide is reached (about Elevation 6725). It lies within what is known as the Tularosa Basin, which extends from this point to the southern limit of the mesa east of El Paso.

From a study of the map of New Mexico, it will be seen that the eastern part of the State is drained by the Pecos River, with its head-waters in small tributaries originating in the mountain ranges of San Miguel County. This stream flows south, crossing the railroad near Santa Rosa and passing well to the east of the Sacramento and Sierra Blanca Mountain Ranges. The central part of the State is drained by the Rio Grande, with its head-waters in the mountain ranges of Taos County. It flows south into Texas, crossing the railroad at El Paso, and passes west of the Oscura, San Andres, and Organ Mountain Ranges.

The Tularosa Basin lies between these two drainage areas. It is flanked on the west by the Oscura, San Andres, and Organ Mountain Ranges, and on the east by the Jarilla, Sierra Blanca, and Sacramento Mountain Ranges.

According to a rational conception of geological reports, the present Tularosa Basin was, in ages past, the peak of a great uplift which divided the drainage basins of the Pecos River and the Rio Grande. Subsequent settlement created a low valley with rough and rocky mountain ranges on either side and from the deposits of ages, this basin was formed as a gently rolling mesa. The rock strata of the mountain ranges on the western side of the basin slope toward the west and those of the mountain ranges on the eastern side slope toward the east. Thus, the seepage water from the western range finds its way into the Rio Grande drainage area and that from the eastern range flows into that of the Pecos River, leaving a gulf of barrenness approximately 60 miles wide and about 150 miles long, which is without a drainage outlet of any kind.

The foothills of the surrounding mountains and the floor of the Basin itself, are underlaid with strata of limestone and gypsum deposits, while the surface is highly impregnated with salts and alkali. Extending 10 or 15 miles west from Coyote, N. Mex., in Lincoln County, there is plainly visible an ancient lava flow from a volcano now extinct. This lava flow continues south parallel to the railroad for approximately 45 miles. At this point, a small stream emerges from beneath the lava bed. The water, however, is so impregnated with salts, gypsum, and alkali as to be unfit to water stock, for domestic use, or for use in steam boilers. Immediately south of the lava bed are extensive beds of powdered gypsum, which offer a striking contrast to the black lava flow when viewed from a distance. The Tularosa Basin has the average rainfall of a general desert country. It is said that this area constitutes the largest inland basin on the North American Continent with absolutely no run-off.

*Bonito Water Right.*—This right is one of appropriation from the waters of Bonito and Eagle Creeks. These creeks constitute a part of the Hondo River drainage area, which flows into the Pecos River near Roswell, N. Mex. The water has its source in the upper reaches of White Mountain Peak (Elevation 12 000) which is a part of the Sierra Blanca Range. The lower part of this mountain contains vast deposits of gypsum and limestone strata, both of which are soluble in water and, when dissolved, produce a hard water that has a tendency to form hard scales when used in steam boilers. The upper part of the mountain is composed almost exclusively of a hard granite formation which contains little or no soluble matter.

Prior to the diversion of this water for boiler use, the railroad had taken water from the Pecos River and from drilled wells. The water thus obtained was unfit for boiler use, and efforts to treat it chemically failed to the extent that the treating plant and the Pecos River supply were abandoned. The water from Bonito and Eagle Creeks is admirably suited for boiler use since it comes from the melted snow on the mountain and contains only a slight chemical content. This water is conveyed by a gravity pipe line, from intakes on Bonito and Eagle Creeks to the Nogal storage reservoir. From the reservoir, it flows by gravity to the railroad at Carrizozo and Coyote, N. Mex., a total

distance of approximately 46 miles. From this point the water is pumped north along the railroad to Vaughn, a distance of approximately 100 miles. The Nogal storage reservoir has a capacity of approximately 400 000 000 gal.

At the time the carrier decided to develop this water for railroad purposes, a part of it had been appropriated by farmers, who were putting it to beneficial use by irrigating the small farms in the valleys along the creeks. The quantity of water thus used is unknown, because no regular system of measurement had been practiced. In 1907, the carrier purchased all the irrigated lands on Eagle and Bonito Creeks as far east as the Fort Staunton Military Reservation, and abandoned the use of water for irrigation purposes in order to divert the water into the pipe line.

The carrier, by purchase and appropriation, completed its title to 5 sec-ft. of water from Bonito Creek and obtained authority from the State to change the point of diversion and to convert the water from irrigation to railroad use. It also perfected its title to 6 sec-ft. of water from Eagle Creek with the right to use it for railroad purposes. The only adverse user of water from these creeks is the Military Reservation, which is entitled to 89 000 000 gal. annually. Under an agreement with the Federal Government, the carrier constructed a branch pipe line about 2 miles long, to and for the use of the Military Reservation.

At the time this appraisal was made, the annual flow of Bonito Creek was more than the quantity of water to which the carrier is entitled, while the annual flow of Eagle Creek is insufficient to enable the carrier to obtain its legal share of water. Thus, the water to which the carrier is entitled is 11 sec-ft., or 2 596 000 000 gal., while the water actually available to the carrier is:

Bonito Creek..... 5.000 sec-ft., or 1 180 000 000 gal.

Eagle Creek..... 3.346 " " , or 799 000 000 "

Total ..... 8.346 sec-ft., or 1 979 000 000 gal.

This is equivalent to 5 395 000 gal. daily.

At the time of this appraisal the full quantity of water to which the carrier is entitled, was not actually diverted from the streams into the pipe line, because that quantity was then in excess of the actual requirements of the railroad. The road, however, is holding this water for future needs, and to provide for storage for use in the dry seasons.

To accomplish this purpose, water is stored in Nogal Reservoir during the period when it is plentiful. The water in excess of the capacity of the pipe lines is permitted to escape through the natural channel of the stream and is used by the carrier's agent for irrigation purposes on the Bonito Farms, which are owned by the carrier. This precludes the possibility of adverse appropriations, through beneficial use by others farther down stream. The writer is informed that these farms are operated at a loss to the company. It was the appaiser's opinion, however, that inasmuch as the carrier should prepare for future expansion of its business, with resulting increased requirements for water consumption, all this water should be considered as "used and useful" for transportation purposes.

*Value for Alternate Use of Irrigation.*—Assuming the availability of sufficient land to consume, for irrigation purposes, the water owned by the carrier, the measure of value of the water right would be the difference between the value of the land with and without water. From a minute study of other irrigation projects in this locality, giving consideration to the similarity in average annual rainfall, it was found that 2 acre-ft. per annum would be the correct measure of the quantity of water necessary to irrigate 1 acre of land. Since 8.346 sec.-ft. is equivalent to 6.043 acre-ft., the water right would irrigate 3.021 acres of land. The difference in value for the land was appraised at \$275 per acre. This produces a value for the water right of \$830.775. The writer concluded that this figure fairly represented the value of the water right for irrigation purposes and would fairly represent the cost to the carrier, if title to all the water was vested in private parties, and should the carrier attempt to purchase the right in its natural condition and develop it for railroad purposes, as of the date of appraisal. This figure does not give consideration to the so-called excess cost of acquisition almost invariably incurred by a railroad in the purchase or condemnation of real property.

Some authorities believe that, inasmuch as the water is used for irrigation purposes for only about one-half the year, the value reflected by this method should be doubled because the carrier makes use of the water for the entire year. It will be observed, however, that the acreage which the water would irrigate, is based on a calculation of the total quantity of water that the carrier would obtain from the flow of the streams, for a full year, under its right of appropriation. In order to utilize the water that runs during the non-irrigating season it would be necessary to collect and store it for use during the growing season. The value of the right would then decrease in direct proportion to the increase of the cost of storage and distribution of the water.

*Original Cost.*—The cost of land, water rights, and pipe line easements (inseparable) to the carrier was approximately \$245,000. The quantity of water to which this purchase entitles the carrier is unknown because its title to the water was afterward perfected through appropriation. This purchase was made sixteen years prior to the date of valuation.

The writer made a close investigation of all water supplies in the Tularosa Basin, and as a result of this study reached the conclusion that no other source of supply was available that could have been secured at a reasonable money outlay. Three mountain streams, from which water is obtained, were found to exist: La Luz, Fresno, and Tularosa Creeks.

La Luz Creek and Fresno Creek originate in the Sacramento Mountains at La Luz, and Alamogordo, N. Mex., and serve the two towns as well as the immediately adjacent farming sections. All this water was appropriated many years ago and it would be impossible to obtain title to it except through purchase of all the land entitled to water, together with the improvements thereon. The railroad obtains some water at Alamogordo for \$500 per month. It is necessary to treat this water before using it in locomotive boilers.

A reservoir on the Fall Ranch, located a few miles east of Three Rivers, N. Mex., impounds the waters from small streams originating in the Sacramento Mountains. The carrier at one time purchased water from this source on an annual basis; subsequently, it purchased a permanent water right.

The carrier owns the water supply at Orgrande, N. Mex., which is taken from the Sacramento River and is conveyed by pipe line to a reservoir on the Jarilla Mountain, from which it flows through a gravity pipe line to the railroad track.

A small stream of water originating in mountain springs, is brought into the Town of Tularosa by open ditch and is owned by the town and its inhabitants.

At other points, deep wells had been drilled to secure water. These ranged from 850 to 1 400 ft. in depth. The water obtained at a depth of less than 1 000 ft. was generally gypseous and contained approximately 3 000 parts of incrusting salts per million. Water below this level, while not extremely hard, had a concentration of soluble salts about seven times that of sea water, and contained calcium and magnesium in large quantities. The well water was generally unfit for boiler use.

Investigation developed the fact that water was sold from the Tularosa supply for irrigation at approximately \$1 650 per water right. A "water right" (which was sold as a part of the land) was found to be that unknown quantity of water required to irrigate 10 acres. While the Tularosa right is somewhat removed from the territory of the Bonito water right, and the two problems are not identical, it is described herein as general information regarding land and water rights in this section.

*Sale of Water Right from the Fall Right to the Carrier.*—This was a sale of a daily flow of 75 000 gal. of water for \$45 000, or at the rate of \$600 per 1 000 gal. daily. The sale price includes a 3-in. pipe line about 2 miles long. The agreement provides that the grantor shall have the joint use of the pipe line with the carrier, but must deliver to the carrier 75 000 gal. daily. The water is delivered at the track, or point of use, and not at its source. The writer applied this sale to the Bonito water right as follows: Available supply, 5 421 000 gal. daily; capacity of pipe line from intakes to Nogal Reservoir, 3 500 000 gal. daily; and capacity of pipe line from reservoir to the railroad, 1 500 000 gal. daily. Delivered at the point of use at the rate developed by the sale, 1 500 000 gal. daily results in a value of \$900 000. From one point of view, the Bonito right is more valuable than the Fall right, due to the fact that it insures a supply of water during periods of protracted drought, and provides for the carrier's requirements upon the expansion of business. On the other hand, the Fall right may be considered as more valuable, for a similar quantity of water, because it is only necessary to pipe this water about 2 miles, while the Bonito right requires a pipe line of 46 miles to the first point of use. The writer is of the opinion that this sale does not represent fairly the value of the Bonito water right, in its natural state. That the value derived by this analysis of the Fall sale is fairly close to that developed for irrigation purposes, is merely a coincidence. Were the carrier's present requirements reduced to one-half and that quantity delivered at the railroad, the value deduced by the application of this sale price would be reduced by one-half.

The carrier received in 1918 an offer from the "Ruidoso Water Users' Association". The Ruidoso River is a tributary of the Hondo and is a few

miles south of Eagle Creek. This offer was for 4 sec-ft., valued at \$300 per acre, on a 3 000-acre basis, or \$900 000. The writer believes that the offer was based on an erroneous assumption. Four second-feet would irrigate about 1 500 acres of land and not 3 000 acres. On this basis, the carrier's water right would be valued at \$1 877 850.

Considering the cost of operation on the railroad prior to the development of the Bonito water right and comparing it to the cost after the water from this source was put into use, and then capitalizing the difference, the result would be a value of approximately \$3 000 000, if it were assumed that all the savings in operating expenses were due to the use of this water. It seems quite probable that the greater proportion of the decreased cost of operation can be directly attributed to the use of the water.

Consideration was given to a number of sales of water rights used for watering stock. These sales averaged \$695 per 1 000 gal. daily, based on the purchaser's requirements of 7 000 gal. per day, which is the quantity required for 560 head of cattle, the maximum number that could be watered from one spring. In purchases of this character, the rancher satisfies himself that he will get a range supply of 7 000 gal. daily; he is not interested in any greater quantity. He would pay the same price for an assured supply of 7 000 gal. daily as he would for a supply several times that amount.

After giving consideration to all the conditions surrounding this water right, its available uses, original cost, future requirements, etc., the writer appraised it at \$913 000, at its source and in its natural state. This was a valuation for rate-making purposes.

C. E. GRUNSKY,\* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The author has attempted to find a simple, generally applicable method of ascertaining the value of a water right. The attempt is laudable, but the effort will be in vain. One main difficulty with the particular method suggested lies in the fact that no rule can be found for apportioning the aggregate value of all intangible elements to the individual elements. Moreover, under the American system of controlled rates, the intangible elements of public utilities acquire value only when rates are fixed sufficiently high. If the earnings will not yield income in excess of operating expenses plus the ordinary cost of money, there will be no intangible values.

A water right, in many respects, is similar to a franchise. It is a grant by the public. It may have indefinite or only a limited life. Its acquisition may have cost something or nothing. Under certain circumstances the water right may acquire a recognized market value, as will be the case if all the water that is available is needed for irrigation.

Frequently in acquiring a water right, it becomes necessary to quiet adverse rights. It may be necessary, for example, to compensate riparian owners for the actual or the prospective damage to their property which would result from an up-stream diversion. All legitimate expenditures made in acquiring a water right (with due allowance for any change which may have taken place in the purchasing power of the dollar) should appear in the rate base.

---

\* Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

The term, "rate base", as herein used, must not be confounded with market value. The aggregate market value of a public utility property results from its earnings and its earnings, in turn, depend on rates. The rates should have some fairly definite relation to the rate base. The value resulting from the rates cannot be used.

Both the Courts and the rate-fixing authorities have definitely assumed the attitude that, when water rights are involved, earnings should be allowed with due consideration of the fact that the water right may have value; but this principle is not thus expressed in the decisions. As the author states, no method has yet been found for evaluating water rights which would be acceptable to the Courts, public service commissions, or valuation experts.

Sometimes recourse is had to a comparison with the cost of developing water in the same general region in which a water right is to be valued. The results are rarely satisfactory, because, in determining such average value, some costs which are above the average and others that are below the average, will be taken into account. It would be evidently absurd to give those whose development has cost in excess of the average a negative value. In places where water is scarce and water rights have been made a matter of bargain and sale, a definite basis can sometimes be found for estimating value. In such cases, the earnings that result from the use of the water become the measure of its value, and this value, in consequence, may assume a wide range. A determination of the value of water rights in such sections of the country will have an effect on the value of rights elsewhere, the question naturally being asked, "Why, if water commands a high price in one section of the country, should it not also command a similar price under comparable conditions elsewhere?" It seems obvious that whoever makes a successful development of water and puts it to beneficial use has done something worth while for society and is entitled to a fair reward. It would not be unreasonable, therefore, to make some allowance in the earnings, preferably based on the ordinary regional costs of developing water which, when capitalized, would be the value of the water right.

If this principle were accepted by the rate-fixing authorities it would result in removing indefiniteness relating to the value of water at its source. The value of a water right, if thus allowed and intentionally recognized and established by the rate-fixing authorities, would not be subject to such uncertainty, nor to the wide range so notable at present. It sometimes happens that, when all the water available is applied to beneficial use, the cost of development of some of the supply is far below that of the remainder. In such cases the value of the water right—if the cost of development is low—may be very large in comparison with the value (at its source) of the other water used in the same district. In such cases, strategic value is recognized, and this can be determined more or less satisfactorily by the comparison-of-cost method.

Another factor which deserves consideration when a water right is to be evaluated is the time during which the right may be exercised, and still another factor is the length of time that it may take to put the water right to full use. Attention is called to these matters merely to show the complexity of the problem of determining the value of a water right. If development is timely and

economically sound, its value—in excess of such part thereof as may be based on cost—is so merged with the value of all other intangible elements that separation is necessarily more or less arbitrary. Personal judgment of experts in each particular case must determine the allocation of the aggregate of all intangible values, which, moreover, is rarely of material significance.

JOHN E. FIELD,\* M. Am. Soc. C. E. (by letter).—The writer regrets that the discussers have interpreted the purpose and scope of the paper as being much broader than was intended. There was no thought of discussing water-right values in the humid region, but in the semi-arid West, where the riparian doctrine had been abrogated and the water was subject to appropriation for beneficial purposes, and where, because the supply was less than the demand, values were created.

Mr. Jacobs concludes that water rights should be included in appraisals, and the writer agrees with him. While in theory the water may belong to the State or the public, the right to its use is a property right. The carrier has a right to the continued carriage and may charge for and derive revenue as a consequence.

If the water right has been acquired by purchase there can be no question of the propriety of including it in an appraisal. In places where it has been filed upon for the use of others (as in a municipal water system belonging to a public service company), it is sometimes contended that, since it belongs to the users—the citizens—such a right should not be included in an appraisal of the company's property; but, in Colorado, the Courts have held that it should be included because the company has the right of carriage. After the point of diversion has been fixed and the quantity and date of priority have been determined, the city cannot change the point of diversion to its own distribution system and deprive the company of its means of revenue. Under the ruling mentioned the value is listed under "carriage right" instead of "water right", and the final result is little changed.

If water that is otherwise running to waste is impounded, it becomes in effect private property. Water that is carried through tunnels or otherwise from one water-shed to another (as is permitted under the decision of the U. S. Supreme Court in the case of *Wyoming vs. Colorado*), is so under control that it, too, is in effect private property. Engineers may safely assume the propriety of including water-right value in general appraisals.

There appears to be one fundamental difference between the writer and most of the discussers in the conception of a water right. Is a water right a tangible or an intangible thing? If it is tangible, then all comment of its inclusion in an appraisal and the necessity of separating it from intangibles, as shown by both Mr. Grunsky and Mr. Jacobs, disappears. Appraisal of water-right values would be much simplified if, instead of using the term "water-right", one used the word "water" only.

The right to use water is tantamount to its ownership; it should be treated as a physical thing with a value to be established the same as for the physical plant. Often the desire is to obtain the actual benefit derived and the actual

\* Denver, Colo.

value to the owner and such value continues until abandonment, which is not to be contemplated as a possibility in most cases any more than the abandonment of the physical works. For example, in Colorado, many smelters and mills which used water for cooling and other purposes, were abandoned. The value of the physical plant then became nil while the value of the right to the use of the water remained almost undiminished. It could be transferred and used elsewhere for similar, or under certain conditions, quite different purposes. Abandonment through non-use is the only way the right is lost and even then it is a question of intention. The abandoned beet sugar factories furnish another example of the permanence of the value of a water right.

In the case of the smelters, had an appraisal been made before 1893—the year of the demonetization of silver and the beginning of the decline of mining—and had the water been considered as merely a franchise and for that reason a small value was given it, then it would seem that the appraisal of the physical plant should have taken possible abandonment into account, for even then the possibility of the demonetization of silver was under discussion. The abandonment of the water right or its forfeiture or cancellation was, in fact, less probable than abandonment of the physical plant.

The writer's suggestion is that the appraiser get at the truth—the real value—first, and then, as far as the necessities of Court decisions require, alter the nomenclature and form of the appraisal to conform to precedent and let the Court alter any parts that may be in doubt.

In regions where water is so thoroughly in the control of the user as it is in Colorado, where it may be bought, sold, transferred, and its use extended and changed, the conception that water is the product that is owned rather than a water right is thoroughly fixed in the lay mind. While Courts and engineers have discussed "rights" in an academic way, in the final analyses they, too, have treated it as a physical thing. In States where the doctrine of riparian rights has been set aside, and water ownership has been vested in the public, the fact that appropriation to beneficial use "shall never be denied", makes the right a very ponderable thing. The act of appropriation for beneficial use and compliance with the regulations pertaining thereto result in removing the ownership from the public to the individual and only the reversion right remains in the public. Right-of-way deeds and grants for railroads generally contain a reversion clause and the value of the right of way is allowed in appraisals to the full extent of actual use and necessity; the value is based on that of similar land in the vicinity. The right of way and the water right in these reversion features are similar.

The propriety of including an indebtedness of \$600 000 in the value of the Fort Lyons Canal has been questioned. The value of the whole property, as determined by taking the market value of a share and multiplying by the number of shares, was \$6 000 000, and this was verified by the President of the Company who also informed the appraiser that there was an indebtedness of \$600 000 which was being paid off gradually by assessments on the shares. The total value when the debt was paid, in theory at least, would be \$600 000 more than it was before.

More details of the method by which the \$2 000 000 value of the physical plant was obtained have been requested. There was available the original cost of the work, including interest during construction, engineering, rights of way, etc. Relative costs of labor and material as of date of construction and of appraisal were ascertained. An examination on the ground was made; the cost of the new structures which had replaced the old ones was determined; and a value was added by reason of the seasoning of the canal, based on an examination of repairs and upkeep during the first years of operation. Indeed, in this case, the cost of maintenance was at hand for each year since the canal was built. From all these items the cost of replacement was obtained, a small sum was added as value of assemblage, bringing the amount to an even \$2 000 000. It was not the Fort Lyon Canal that was being appraised. The appraisal was not a rate-fixing case, nor one to be reviewed by any Court. Its purpose was to ascertain the value of the many water rights of the Company as nearly as possible and approximately correct as a whole rather than as to details; additional expense was not incurred in unnecessary refinements.

Furthermore, the water-right values of three canals (the Fort Lyon and two others) were taken and these were selected for their simplicity of ownership, capitalization, stability of stock values, success in operation, conservatism in management, and progressiveness in improving the character of structures, etc. In short, three of the best managed and most successful canals were selected and the value of a number of water rights of different priorities was obtained and plotted in Fig. 1. With this curve the probable value of any priority in the same water-shed could be "picked off"; and with this probable value as a base from which to work, the values of the numerous canals, pipe lines, domestic supplies, etc., embraced in the appraisal, were determined.

In several cases this probable value was changed as affected by use, soil, locality, abundance or scarcity of water, supply and demand, yield, etc. In fact, the major part of the work of appraisal was not in determining the base curve, but in applying needed corrections. The base curve was valuable, enabling one to show a consistency in results, or good reasons for an apparent inconsistency.

Mr. Jacobs lists numerous factors that have a bearing on water-right valuation. An example of Factor (a) is the difference between the laws of Wyoming and Colorado relative to water being attached to the land. In Wyoming, water may not be transferred and through more economical use, it may not be made to cover a greater area than the permit shows. Except as noted later the title to water goes with the land; its use is comparatively rigid and inflexible. In Colorado, on the other hand, its locus of use may be changed even to diverting it into another canal. It may be made to cover a greater area and, therefore, it is an article which may be sold, the value being largely determined by supply and demand.

Referring to Factor (b), in some States there is an irrigation season. In Colorado, the only time limit is the needs of the appropriator, beneficial use being the limitation of the right. There are, also, canals in which water flows during all but the most severe freezing weather. Moreover, water may be

temporarily stored to be used later in the season. These extra privileges have value and affect the appraisal.

In States that operate under the Wyoming Code, or modifications thereof, the separating of the water values and land values is not generally necessary; but, in Colorado, the water right must be specifically named in the deed to the land if the intention is to let it go with the land.

The writer approves of Factors (c) to (g), inclusive, with the supplementary comments by Mr. Jacobs. As to Factors (h) and (i), it might be added that agricultural uses furnish the alternatives for a domestic supply, and agricultural values influence strongly, if they do not actually fix, the value of a domestic supply. Factor (j) appears to be highly improper when the object of the appraisal is rate fixing. It would not be proper, except for purposes of comparison with other methods, when the value could be found by any other method. The process in this case is merely to start with an answer and work back.

Mr. Jacobs and others call attention to the writer's statement that "whatever amount was paid for \* \* \* old works that were abandoned or destroyed, was added to the cost of the water or water right." The water right was purchased with the knowledge that the old works would not be used, and as far as the purchaser was concerned, the amount he could afford to pay was for the water right only. The seller doubtless included the value of the old works in estimating for what he could afford to sell; but the water right was the only thing of value to the purchaser, so that, in appraising the new works, the value of the water right to the new system of necessity includes the seller's estimate of value of the old works which, at the time of appraisal, are non-existent.

It seems that several discussers have confused the value of water stock or shares in a corporation and the value of a water right as used by the writer. The first is the value of shares as shown by numerous sales over a period of years. It is the market value of the shares. The second is the value which is paid for water without physical works and for water to be transferred to some other system. It is the value of a surplus supply owned by some one anxious to sell, and which he can no longer use with reasonable profit; it is a right which, from some cause, he is compelled to sell, possibly from the danger of abandonment and of forfeit; possibly the price is greater than the nature of his own lands and crops justify him in holding.

Mr. Jacobs states: "As applied to private industry, the logic of capitalizing excess net earnings as a basis for determining water-right values can hardly be questioned." Such a method may be logical, but it might be neither just nor correct. Values as determined by actual sales, by the cost of alternative supplies, and by the values in similar enterprises and conditions, might all point clearly to the unreasonableness of an appraisal on such a basis. In cases where all these possibilities of using other methods are absent and there is no power of rate fixing, then such a method of necessity might be used, not as really fixing the value, but as an element in guiding the judgment toward a reasonable valuation. Instead of raising the value of the water

right beyond a reasonable figure, a large interest return on the investment as a whole should be shown.

The writer once made an appraisal of water which was used for condensing purposes and was immediately returned to the river. The saving in coal, operating cost, and investment was cut about 33% below the estimated cost of non-condensing engines. Underground water could have been pumped at a relatively small expense; this right of use could have been abandoned and another filing of almost equal efficiency could have been made. The net earnings of the mill, through the use of the water, were enormously increased, making successful competition possible; but the value of the water right in itself was small.

The writer agrees with Mr. Jacobs that "no single method of valuation can be rigidly applied \* \* \*". In all cases all possible methods should be used; their importance and applicability should be weighted, and the final conclusion determined in accordance with the appraiser's judgment.

In a number of the discussions the writer's statement that "stored water" has little more value than "unstored water" has been criticized. The writer should have said that "water available for storage" has little more value than that available for direct diversion and use of the same date of priority. Much stored water is sold year by year in Colorado, not always to the same user, but to any one who has need of it. The price is fixed by the supply and demand at the time of sale. In a year of large flow, it has little value. Generally, the seller insists on a reasonable return on his investment in the physical works over a period of years, while the purchaser considers the value to him as an element that helps to grow, save, or increase his crops. When the average charge is great or becomes unreasonable, the use is curtailed by more careful handling and avoidance of waste, or by the construction of additional storage facilities. Such cost at the time of construction is almost the full value of the water, leaving little or nothing as the value of the water right. The gradual advance in values and of returns on such an enterprise accrues to the value of the right.

Mr. Tibbetts states that: "The few public utilities serving water in California seldom have a total stock value equal to that of their appraised physical properties \* \* \* although it is recognized that their water rights have substantial values \* \* \*". He does not state whether such utilities have mortgages, bonds, or other debts outstanding. If there is indebtedness, then it should be added to the stock value as the writer did in the Fort Lyons case, and, by the method proposed, it might be found that the water right had a value. There are enterprises, the physical costs of which were more than the value of the water delivered, as in some of the reclamation projects. This excess of cost over value must be recognized by the appraiser, and corrections made. Such a project should not be taken as a basis for determining values or rights on other projects. On the other hand, if a project, such as this, is being appraised, then the method proposed in the paper appears to be eminently suitable. The values of the water right would be determined by examining other projects, and these need not be confined to public utilities, but private, municipally

owned, and mutual projects could be used as a basis for constructing a curve of water-right values. The result on a project such as that mentioned by Mr. Tibbetts would show that the investment in physical works was too great for the obtainable revenue and also the amount of the excess.

Mr. Tibbetts states that, "if he were to purchase a large amount of stock \* \* \* he would first appraise the physical properties and \* \* \* water rights \* \* \*". That is exactly what the writer proposed. He ascertained the values in other projects and applied those values to the properties being appraised.

Mr. Tibbetts "sees no reason why the value of water for domestic purposes should not be based on the city's necessities and on what the city can afford to pay." The reasons are that agricultural water can be purchased for domestic use (as was done in Owens Valley) at agricultural prices, and that there is no practical limit to what a city can afford to pay. Mr. Tibbetts in this connection cites Southern California. If agriculture by irrigation in Southern California should absolutely cease, there would be no need to bring water from great distances for domestic use, and the demand for such use would dwindle with the dwindling population.

Mr. Tibbetts' remarks, under "Land Increment Value", are particularly pertinent. A bonus to the land owner should be included in "land increment value". At this time in particular it is necessary at least to hold out the hope to the man who takes a raw piece of land and develops it into a going concern, that he will receive a substantial advance in the land value over and above cost and labor. It is the task of determining the size of this bonus that makes land increment value difficult as a basis for determining water values and as a means of allocating the difference in value of adjacent unirrigated land and the irrigated land, to the land, the water, and the bonus. Mr. Hedke calls this "margin".

In Fig. 2, Mr. Tibbetts shows the average yield and an assumed water demand. It should be recognized that the yield curve determines in large measure the demand curve, because with a given yield curve the user adjusts the character of his crops, methods of farming, type of physical irrigation works, and the acreage irrigated to conform approximately to the yield curve. It is almost invariably true that the yield and demand curves are similar, the difference being more in position than shape, because the demand curve is later in point of time. The construction of reservoirs is the means generally used to make the demand curve and the supply curve more nearly coincident.

Referring to Mr. Scoby's discussion, it is well recognized that shares, stock, rights, and even measurements of water, such as the inch, vary widely in meaning. To avoid confusion, the writer adopted volume delivered as the measure, and he thought he had avoided the necessity of using the variable time element of an irrigation season by adopting the full year as the theoretical maximum. The use of the full year could not have been avoided because many of the rights to be appraised are used for 365 days. Had some arbitrary irrigation season been adopted, such as 180 days, it would have been necessary to give some of the properties a delivery coefficient of 200%, and

the meaning of 200 per 100 is paradoxical, confusing, unnecessary, and complicated.

Mr. Hedke states that "it is natural, therefore, that Mr. Field \* \* \* should complacently open an unsettled subject without ever mentioning ownership." The writer admits also to complacently assuming that values of water rights should be included in appraisals, that they have value, that the user to all intents owns the water, and that they are susceptible of appraisal by fairly rational means, simple in principle, but difficult in application.

Mr. Grunsky states that efforts to find a simple, generally applicable method will be in vain, the main difficulty being in allocating the intangible values to the individual elements. This is true; all appraisals are difficult, but they are based fundamentally on the physical plant which can be appraised in a rational way. To the writer a water right appears to be a physical element, a tangible and not an intangible thing.

Mr. Stivers discusses interestingly various methods of appraisal and the Court decisions thereon. He states that the method proposed in the paper is unsound, because it is not a generally accepted method. Any method, however new, untried, or even revolutionary, if it is reasonable, and is evolved in a rational way, will doubtless be accepted by the Courts. It is the duty of the appraisal engineer to use a rational method regardless of other and "generally accepted" methods. The Courts have modified, changed, and even reversed previous opinions too often to cause an engineer to hesitate to use a method he believes to be good. Indeed, the use of a method that is questionable with other methods for comparison and guidance to final conclusions, is advisable. That engineer is wise who studies Court decisions. Through them he obtains ideas and "food for thought"; he finds methods analyzed and learns the reasons for using them; they aid him in developing the judicial attitude; but to say he is bound by such decisions—that he must accept them as final—would be to stop progress in the evolution toward better methods.

Mr. Stivers has given an interesting account of an appraisal of a water right owned by a railroad company in New Mexico, and has used a rational method for its determination. When based, as it is, on an assumed duty of water and on a stated difference in land values before and after the land was deprived of water, the method is correct. The analysis of the result is confined to the correctness of the determination of the duty of water and of the difference in the land values.

It seems that the value of the non-irrigation season flow should have been specifically determined by ascertaining the cost of storage for agricultural purposes, and whether or not such an expense was justified. Deductions in the quantity stored, by reason of evaporation, seepage, and other losses, should be made, and the availability of land and its return in crop value should be studied. The amount for which the railroad company could have sold the water to some other users, and what those users could afford to pay, would fix the value of the winter flow more certainly than if based on the value of the irrigation season supply as was done by Mr. Stivers. If this estimated sale price of the stored water exceeded a reasonable return on the investment

plus the cost of maintenance and operation, then the winter flow would have a value, and the amount of the excess earnings would be the basis of that value.

In referring to the temporary use of the water, Mr. Stivers states that the farm operations of the railroad do not pay. If the same result should obtain under good management by others (farming undertaken by a corporation as a side line, and as a matter of policy and necessity, seldom pays), then the values given to the winter flow are erroneous unless justified by values obtained by some other method, and some demand other than agricultural.

In conclusion, it appears to the writer that, while the laws governing water rights vary in the different States, their customs and decisions are more nearly in harmony. In Wyoming, where the Code differs radically from that in Colorado, the Court decisions are generally in harmony with, if not actually based on, earlier Colorado decisions. Many water rights in Wyoming were acquired under territorial laws. These, in particular, have been treated as, and have a standing similar to, rights in Colorado. The tendency in Nebraska, Kansas, Wyoming, and New Mexico is to follow the Colorado decisions. Practice in Colorado is based largely on decisions, which cover almost every phase of every water-right question. They have undergone the test of time; they have been modified when advisable, and, therefore, they present to other Courts a well established and practical solution of most of these questions. While examples and cases applicable particularly to Colorado have been used in argument and illustration herein, they are believed to be largely applicable to other States.

All those who have discussed the paper have shown unusual familiarity with water, its uses, and the problems involved in considering, not only values, but uses, customs, laws and practice.

THOMAS R. NEWELL, E. B. DEBLER, AND G. CLYDE BALDWIN.

\* Presented at the meeting of the Irrigation Division, at Denver, Colo., July 14, 1927.

## TRANSMISSION AND DELIVERY OF RESERVOIR WATER

BY G. CLYDE BALDWIN,\* M. AM. SOC. C. E.

Throughout the early stages of irrigation development in the West reservoirs were of little consequence. Land was watered by direct diversion from the natural streams with small effort and at little expense. The success of the pioneers naturally attracted others; more difficult enterprises were undertaken; and following the enactment of the Federal Reclamation and Carey Acts, really large-scale undertakings were initiated. By this time, also, the low-water flow of many of the streams had proved to be insufficient to supply all demands. For this reason, and because of the feasibility, under these laws, of financing the construction of dams and other necessary works of considerable magnitude, storage reservoirs began to play a part of constantly increasing importance in all reclamation plans; until, to-day, they are usually considered to be the foundations upon which most new irrigation projects must be based.

Low unit storage cost, together with the physical possibility of making gravity deliveries, chiefly governed the location of these early reservoirs. Scant consideration was given to the other difficulties which might later be experienced in connection with their operation.

Where the selected impounding basin is located close to the irrigable lands, on otherwise dry channels, or on small streams where no conflict with other water rights exists, these operation or delivery problems are comparatively unimportant. They become very real and worthy of consideration, however, where the storage must be transmitted for long distances down the natural channel of a large stream, most of the normal flow of which has been awarded to other and earlier appropriators.

Situations of this character are now to be found in most of the Western States, but probably none is more complicated or involves the administration of such large quantities of water as that of the Upper Snake River Basin in Idaho and Wyoming. In that portion of this area which, for water distribution purposes, is administered as a single unit, four major and several minor storage reservoirs are in operation. Without taking into consideration small diversions on the upper reaches of the streams, which are relatively isolated and where net consumption of water is usually small, water is diverted from the river and its larger tributaries through about 120 principal canals.

The four large reservoirs are Jackson Lake, situated at the upper end of Jackson Hole, Wyoming, and only a few miles south of Yellowstone National Park, with a capacity of 847 000 acre-ft.; Henrys Lake, near the head-waters of the North or Henrys Fork of Snake River, the capacity of which is about 75 000 acre-ft.; American Falls, on the river just above the Town of American Falls, Idaho, where the full capacity of 1 700 000 acre-ft. is available for use

\* Hydr. Engr., U. S. Geological Survey, Idaho Falls, Idaho.

this year (1927), the first since the completion of the dam; and Lake Walcott, created by the Minidoka diversion and power dam of the U. S. Bureau of Reclamation, where about 107 000 acre-ft. is normally impounded and can be used, at the sacrifice of power head, in times of urgent need.

The canals range in size from those with a capacity of only 1 or 2 sec.-ft. up to one of more than 3 600 sec.-ft. The maximum for the entire group amounts to nearly 30 000 sec.-ft., while the total diversions from May 1 to September 30 in a normal water supply year equal almost 6 000 000 acre-ft.

Henrys Lake Reservoir is owned and utilized entirely by canals in the vicinity of St. Anthony, Idaho, while Lake Walcott belongs to the adjacent Minidoka Project. Roughly, 15% of the combined storage impounded in Jackson Lake and American Falls Reservoirs belongs to canals in the so-called Idaho Falls Section; 14% to the Minidoka Project; 38% reserved for as yet undeveloped enterprises; 2% to the Idaho Power Company; and the remainder, or 31%, to the Twin Falls-Jerome Canals which divert at Milner Dam, the extreme lower end of State Water District No. 36.

The natural stream channels must be used for carrying all stored water, except that impounded in Lake Walcott, from the reservoirs to the points of final diversion and use. In the case of Jackson Lake water, this means transmission of more than one-half the total volume for a distance of about 300 miles, past the head-gates of the Idaho Falls region canals, and on through the American Falls and Lake Walcott Reservoirs.

Normal flow water rights have been decreed at the canal head-gates, but stored water, on the other hand, is acquired at the reservoir. Both the States of Wyoming and Idaho provide by statute for the use of stream beds as channels for the conveyance of stored water. However, there is no prescribed basis for converting a reservoir right into a right at the point of diversion many miles down stream. Every one agrees that some deductions should be made for transmission loss, but there is a wide divergence in views as to how this loss shall be determined. This ranges from a minimum proportional charge based on estimated additional evaporation and seepage resulting, respectively, from the extra exposed surface and wetted perimeter caused by the storage run, up to a direct proportional quantity tax through each small section of river channel where net losses are known to occur, with no corresponding credits in sections where the river shows a net gain.

During the first few years after the completion of the original temporary dam at the outlet of Jackson Lake, attempts were made to deliver the storage to the lower valley in a series of flush heads. Prior to the arrival of each of these flushes, canals in the Idaho Falls area were staked, and river riders were employed to make certain that this normal draft was not exceeded during the storage run. Under this delivery plan Lake Walcott was operated as a catch-basin and equalizing reservoir. This method resulted in net storage losses amounting to between 25 and 30%, while the alternate high and low river stages were very destructive to the less permanent diversion dams along the stream and made difficult the maintenance of any uniform flow in the canals. Consequently, it was unsatisfactory alike to stored water and to normal flow users. Beginning in 1912 this method was abandoned in favor of a continuous

flow system which, with certain modifications pertaining chiefly to transmission losses, has been in use since that time.

Under the latter system the rate at which storage is released from the reservoir varies with the needs of the stored water users, but abrupt fluctuations of any magnitude are avoided. Allowance is made for time of transmission and loss in transit. Then, the intervening canals having normal flow rights are regulated in accordance with the decrees to insure proper deliveries each day. The daily determination and frequent regulation of flow in each canal, as well as the maintenance of continuous records at numerous river points, are required.

For many years, the amount to be charged against this storage as transmission loss continued to be subject to dispute and was provocative of much dissension as to stored and normal flow, or on geographical lines, between lower and upper valley water users.

Numerous partial investigations of different phases of this problem were authorized from time to time. Most of these, because of the experienced and disinterested personnel obtainable, were conducted by, or under, the supervision of the Water Resources Branch of the U. S. Geological Survey. These investigations served gradually to accumulate certain facts concerning river losses and gains and the reasons therefor. The problem is an extremely complicated one, however, involving many variable quantities, so that even if much more money were expended and the investigation made comprehensive over a period of years there appears to be some doubt as to whether a transmission loss schedule can be evolved, which will be absolutely equitable under all conditions.

Meanwhile, deliveries have been effected from year to year under what might be termed compromise schedules, based partly on investigation or fact and partly on mutual concession by the different classes or groups of users. Actual applied losses from Jackson Lake to Blackfoot have ranged from 5% in some of the earlier years to about 15%, with the average for recent years about 13 per cent. These are subdivided as follows: From the outlet of Jackson Lake to Heise, Idaho (canyon section),  $2\frac{1}{2}\%$ ; from Heise to Lorenzo (so-called Snake River cone), actual percentage loss each day as determined from the average of the two preceding days' records, with a minimum charge of 3%; from Lorenzo to Woodville (section where a net gain in the river is usually noted),  $\frac{1}{2}\%$ ; from Woodville to Blackfoot (heavy loss section), 6 per cent.

Another troublesome item is the equitable segregation of stored water from normal flow at the outlets of the respective reservoirs. For Jackson and Henrys Lakes the practice of relying chiefly on the reservoir capacity tables for the determination of the amount of storage released daily, has been followed for a number of years. Special investigations indicated that while this method does not accurately apportion all the factors that make up the total outflow at all times and under all conditions, it is, in general, a reasonably fair plan of distribution and has the advantage of being easily operated. This method automatically credits the normal flow with all increments from bank

storage return in lieu of the old natural lake storage and the extra water-surface evaporation.

The situation at American Falls is somewhat different. Here, there was no initial lake prior to the construction of the reservoir and little is known as yet concerning the relative values of such items as deep percolation loss and bank storage return, while the stored water will be subject to an evaporation loss charge for practically the entire exposed water surface. This reservoir is situated in a section where the river previously showed a net gain from large springs and ground-water sources. Data obtained by the U. S. Bureau of Reclamation during the summers of 1924, 1925, and 1926, suffice to determine that a little more than 50% of this gain comes from surface streams which may be gauged even under full reservoir conditions and that the total inflow or gain through the reservoir is quite consistent in its fluctuations with the changes noted in the measurable half.

The normal flow which should pass the outlet gates can be approximated, therefore, by adding to the water which enters the reservoir through the main river channel the product of the daily measured gain and the predetermined coefficient. This method is both laborious and expensive because it requires daily measurement and summation of the flow of about twenty-five rather inaccessible streams. Furthermore, there is no assurance that a coefficient which was applicable in one year will also apply in another; but it affords a determination that is independent of evaporation, percolation, bank storage return, and other such items, all of which were studied during the summer of 1927 with the idea of evolving a simpler procedure for the future.

The use of space in Jackson Lake Reservoir for the storage of decreed water rights and the later release and delivery of the water thus held back were authorized by mutual consent of all water users in 1924 and again on a more restricted basis in 1926. This plan encouraged rotational use of water and undoubtedly helped to promote higher duty usage during those years when the total supply was deficient. Its adoption adds many complications to the work of water administration and because of the departure from normal procedure the plan is perhaps subject to attack on the question of damage.

The human relations feature of the water distribution work is probably more important than any other phase. It is often said that in an irrigated country an otherwise upright man will not hesitate in times of drouth to steal water and that the most peaceable citizen under ordinary conditions may quickly become one of the most violent if he thinks his water rights are being attacked or infringed in any way. Certainly, water disputes are easily started and sometimes become very bitter.

In this respect the Upper Snake area is not materially different from other sections; but there appears to be a growing tendency to try to adjust these disputes without violence and without recourse to long drawn out litigation. This attitude is believed to be largely attributable to a so-called "Committee of Nine" the members of which are elected each year by the water users to act as advisers to the district water master. At any rate this Committee has been most helpful in making contacts between the administrative officer and the individual water users. It passes on the annual distribution expense budget

and on all matters of policy that are not clearly defined or established. In many other respects it may be compared to a Board of Directors for the Water District, of which the Water Master, or Deputy Commissioner of Reclamation, is the General Manager.

The writer has held the latter position, as well as that of Special Deputy in charge of stored water delivery, since May, 1919. In addition, he has acted as District Engineer for the U. S. Geological Survey in charge of hydrometric work within the same area. In March, 1923, and, subsequently, each year he has also been elected to the position of Water Master, thus further centralizing the water distribution administration. A skeleton organization consisting, in addition, of two engineer assistants and a clerk, is maintained throughout the entire year while deputy water masters, hydrographers, and other employees are added as needed during the summer months. A limited edition of a special report of each year's operations is prepared during the winter while stream-flow data are also made available through U. S. Geological Survey Water Supply Papers and the biennial reports of the State Commissioner of Reclamation.

While of necessity details have been largely omitted in this outline and many important phases of the work have been touched only briefly, it is sincerely hoped that this procedure, which has stood the test of many years' actual operation, may be of value in other sections where similar problems are encountered, or where they may develop with more complete water usage.

## ADMINISTRATION OF STREAM FLOW

BY EDWARD HYATT,\* M. Am. Soc. C. E.

## SYNOPSIS

In this discussion of the administration of water supplies under State control in the seventeen irrigation States, special reference is made to California. The conflict between the opposing legal principles of riparian and appropriative water rights has retarded and penalized water development in that State. Efforts are under way to ameliorate this condition.

## COMPARISON OF WATER CODES

In seventeen Western States irrigation is generally practiced. These include Texas, Oklahoma, Kansas, Nebraska, North Dakota, South Dakota, and all States west thereof. Of these, all but Kansas, South Dakota, and Montana have adopted water codes providing for State administration of the distribution of the waters of their stream systems through the agency of water masters or water commissioners. While the fourteen codes adopted show considerable variance in nomenclature and in points of procedure an analysis reveals substantially the same underlying purpose in each, which is to make possible effective State control of the distribution of water.

Each code provides for the division of the State into water districts. In Colorado and Texas this division has been arbitrarily made by legislative enactment and, in all other States, the water districts are created as needed by the State Water Commissioner, State Engineer, or the official in charge of water matters. In three States the water masters are appointed by the Governor; in one State the water users elect the water masters; and in all others they are appointed by the chief water official. In eleven States the water master has the power of arrest and, in ten, interference with his acts constitutes a misdemeanor. Twelve of the fourteen codes give the water user the right of appeal from the actions of the water master; seven to the Superior, District, or Circuit Court, according to the judicial structure of the States, and five to the State office in charge. In three States the compensation of water masters is fixed by the Legislature, in one by the water users, in one by the county commissioner, and in the remaining nine by the State office.

Financing the work of distribution is accomplished in various ways. In one State—Nebraska—it is paid from general State funds and, in five others, from general county funds. In 1927 the California Legislature passed an act by which half the cost will be met by the State and half by the water users. In the remaining seven States the charges are met in different ways, but in each case are later assessed back against the actual water users. The basis of apportionment of cost among the water users is,

\* State Engr., Sacramento, Calif.

in most cases, the respective quantities of water delivered. In one State—Nevada—it is on the basis of the established water rights.

The methods of administration for the various States are listed in Table 1.

#### CALIFORNIA PROCEDURE

According to the 1920 Census, the irrigated area in California exceeded that in any other State and was more than double that of any other State except Colorado and Idaho. With the statutory water codes approximately the same in all the States and with the greatest irrigated area in California, it would naturally be expected that California would be found in the lead, or nearly so, in the matter of efficient handling of its water resources, particularly in the matter of distribution. This, however, is far from being the case. In both adjudication and distribution California is far behind such States as Colorado, Wyoming, Idaho, and others. The reasons for this condition are not far to seek. The principal obstacle lies in the recognition by California of the riparian principle.

#### RIPARIAN RIGHTS

Apparently, most of the inter-mountain States have escaped the riparian rights doctrine and its consequences entirely. This rule has caused no end of trouble, and has been a great handicap to California. Years of effort and millions of dollars that should have been put into development have been expended in conflict and litigation. A general uncertainty has been thrown about the legality of water rights, which has added greatly to the difficulties in the way of water projects.

A riparian right rests on land ownership and inheres in land bordering on a stream of water. The right as defined by the California Courts does not depend on use, nor does it cease with disuse; it is superior to an appropriative right except in special instances and is not limited to reasonable use as against the appropriator. It is contrary both in theory and practice to the doctrine of appropriation of water, which rests entirely on use and is, of course, opposed to any general water conservation measures such as have to be resorted to in the West.

#### HISTORICAL

California's water law history has been unfortunate but interesting. The appropriative doctrine was established in the "Fifties" by the miners as a necessity of the time and has been recognized by the Courts from that time on, although not until 1913 was it clearly set forth by statute. The riparian theory was adopted by reference when the common law of England was made the rule of decision in the State by statute of 1850.

The fact that there were two doctrines of water law, contrary in principle, naturally led to many disputes. Neither being adequately set forth by statute such disputes could be settled only by Court decisions. Therefore, in sixty years, about seven hundred State Supreme and Appellate Court decisions on water matters have been given. Covering a range of climatic conditions from humid to arid and such a great length of time, the deci-

sions are naturally overlapping and conflicting; however, they are in the main not subject of change by legislation, and to a considerable degree constitute the water law of the State. It is of interest that the other irrigation States likewise adopted the common law of England, but that nearly all their Courts followed the lead of Colorado and abrogated the common law provision on the general ground that it was unsuited to the needs of the State. If the California Courts had adopted this same attitude the State would have avoided this difficulty.

#### CALIFORNIA WATER CODE

On account of conflict between the riparian and appropriative factions it was impossible for many years to enact even an appropriative code, but in 1913 this was finally forced through for the initiation of appropriative rights. In 1917 an adjudication procedure was added and in 1921 the distribution feature. The distribution statute was incomplete in that compensation for water masters was not covered, and it was not until the 1927 Session of the California Legislature that the distribution procedure was made workable by the addition of a compensation provision. This law took effect about August 1, 1927.

#### ADJUDICATION METHODS

Under the 1917 amendment two methods of adjudication of water rights were provided: First, a complete procedure for the adjudication of appropriative rights patterned after the Oregon Act, which was thought to be the best then in existence; and the second authorizing judges of Superior Courts to transfer water litigation to the Division of Water Rights for investigation as referee. The results under these two modes have not been as anticipated. The adjudication procedure provided in the Act is a complete and admirable one and effective in a case involving only appropriative rights; but when the *bete noire* of riparian rights enters the picture the situation is changed. This method cannot determine riparian rights, and, as any adjudication, to be satisfactory, should take account of all rights, it is apparent that this type of action will fail where riparian rights of magnitude exist.

To its sorrow California has found that they exist almost everywhere. A good attorney can develop for a client riparian rights which the client himself would never have thought of claiming. Mainly on this account in the last few years most of the adjudications have been handled through the Court reference method. To accomplish this a suit is filed, sometimes a friendly suit, and then by stipulation the case is referred to the Division of Water Rights. In this way rights of all classes—appropriative, riparian, and prescriptive—are included, because the Court has jurisdiction over all of them, and the Division of Water Rights in acting as the Court's referee can properly take account of them. After making its investigations the Division reports back to the Court, often presents a suggested form of decree, and the desired result, that is, a workable adjudication of rights, is accomplished.

This method is not without its difficulties, however, as it is usually necessary to re-frame the pleadings to the suit, so that all parties cross com-

plain, and to have the Court order into the case all users of water from the stream in question, not already parties to the suit. Therefore, unless the judge and the various attorneys are actively interested in seeing that a true adjudication results, some difficulty is apt to be encountered.

#### ADJUDICATION RESULTS

Adjudication proceedings on twenty streams in California have been undertaken by the Division of Water Rights, fifteen under Court reference and five under the adjudication procedure provided in the statute. Nine have been completed and eleven are pending. While three stream systems of considerable magnitude, the Stanislaus, Shasta, and Whitewater Rivers, are being adjudicated, the other proceedings have been principally on smaller systems, mainly in the northern part of the State. The increase in activity under the Court reference method has been marked in the last few years.

#### DISTRIBUTION

The first instance of distribution of water under the provisions of the 1921 Statute occurred in 1922 when the water users on West Carson River, an interstate stream which flows into Nevada, petitioned for and received service in conformity with that law. Since then, as additional adjudications have been completed, the number of water masters has grown to six, besides some assistants. As no method of compensation was provided, it has been necessary for the water users to subscribe voluntarily the greater part of the required funds, the State lending some aid. This method is of course unsatisfactory and has retarded the extension of water master service. As already indicated, this difficulty has now been removed with the adoption of what is believed to be an equitable method of payment for the water masters.

In some instances the necessity for a responsible official in charge of distribution has been so great that agreements have been effected under which a water master could operate. In several cases adjudications were under way but not completed; and in others the complications of the situation were so great that adjudications by any method were deemed practical impossibilities and mutual agreements were reached among the ditch owners, which permitted distribution.

The outstanding example in this latter class is Kings River, the most important irrigating stream in California. Approximately 700 000 acres are irrigated from this source, and the direct flow rights and diversion capacities amount to 10 000 sec-ft., a flow which obtains in the ordinary season for a very few weeks and which is not reached in a dry season. About 150 000 people, practically all dependent on the results of agricultural pursuits, live in the area supplied by the waters of Kings River, showing the importance of the subject.

This river is an excellent example of the confusion caused by the conflict between the two principles of water rights. More than 200 lawsuits had been filed affecting the water rights of Kings River and more than 40 actual Court decrees entered, which, however, were so complicated and im-

possible of reconciliation that they could not be used as a basis for either adjudication or distribution. After several years of investigation a schedule devised along the lines of past use was suggested by the Division of Water Rights for Kings River and was accepted temporarily by all parties. Under this schedule the water has been successfully distributed for a number of years.

A somewhat similar situation exists in Sacramento Valley. Here, as an additional problem, the low-lying lands around San Francisco Bay are endangered by salt water entering from the sea. Formerly, the flow of Sacramento River was sufficient to keep the salt water back, but with the development of agriculture in the Upper Sacramento Valley this is no longer the case. A water master with limited authority is in charge of Sacramento Valley.

Speaking generally, both adjudication and distribution are in their infancy in California. As the advantages are demonstrated by the examples at hand there is a greater demand for such regulation. If the riparian question could be satisfactorily adjusted there would be, in the writer's opinion, a development along these lines comparable to that which has taken place in many of the other Western States. California has not of course built up an organization similar to that in Colorado, Wyoming, or Idaho. Its water-master efforts thus far have been more or less sporadic and of small consequence compared to other items of the Division of Water Rights' work. Many cases come up as emergencies for short times only and so far the work has not been extensive enough to warrant a separate organization. The time is approaching, however, when this will have to be provided and it is gratifying to have available the experience and precedent of the other States that have studied these problems for so many years.

#### HERMINGHAUS DECISION

Returning to the most important question affecting California water rights, that of riparian rights, the State Supreme Court during the past thirty years had considerably narrowed this principle by limiting riparian areas by insisting, in some cases, on actual need of water. However, in the latest case, that of *Herminghaus vs. Southern California Edison Company*, the Court in a lengthy opinion made a sweeping declaration in favor of riparian owners, stating among other things that the use of the full flow of a river in order to afford the natural diversion of a small part of its waters through overflow was a reasonable riparian use. In the particular case in question this meant that the flood flow of the San Joaquin River, 20 000 sec.-ft., could be required for the natural irrigation of the Herminghaus lands while it was admitted that 180 sec.-ft. would be sufficient if artificial means of diversion were used. This principle would mean in effect that storage could not be made on a stream where a lower riparian owner demanded the full flow of the stream for the natural irrigation of his lands.

As on its face this decision appeared to make it possible for riparian owners to prevent up-stream storage, it has been widely discussed and solutions of various kinds have been advanced. For the past six years the State of California has been conducting investigations with a view to devising a plan for the most complete utilization of its water resources. The key-

note of such a plan is the storage of flood waters, as the natural flow of the streams of the State during the irrigation season is already practically taken up. This decision then became of importance to the State itself in this connection.

The 1927 Legislature actively took up the question and considered many proposed Constitutional amendments designed to clear the situation. After a hard battle in the Legislature one such amendment was passed. It is known as Constitutional Amendment No. 7 and provides that water rights in California shall be limited to such water as shall be reasonably required for the beneficial use to be served and shall not extend to unreasonable use, unreasonable method of use, or unreasonable method of diversion. While this measure is aimed directly at the doctrine declared by the *Herminghaus* decision, it will be seen that its effect will depend entirely upon the definition of "reasonable" as applied to methods of diversion and use of water. This can doubtless be clarified by subsequent legislation if the amendment is adopted.

The writer can well imagine that to water users in Colorado, Utah, Wyoming, and the other States which have so fully utilized their water resources, it is incomprehensible that the State of California should countenance such a wasteful legal policy as that set forth in the *Herminghaus* decision.

## PRESENT TENDENCIES IN WATER ADMINISTRATION

BY GEORGE M. BACON,\* M. AM. SOC. C. E.

The discussion of present tendencies in water administration will be confined to the practice and experience of the State of Utah. It is believed that as much value will attach to a specific case as to a general treatment of the subject. By considering a concrete example, and comparing other experiences with it, lessons of value can be drawn as easily as by trying to deduce such lessons from a more general and broad treatment of the subject.

When the pioneers first settled in Utah and commenced to irrigate, the problem of distribution was one of mutual agreement. Later, as the waters of the various streams became fully appropriated, the inevitable litigation set in, resulting in the usual practice of having the Court that decided the rights administer them through a water commissioner of its own appointment. With the spread of irrigation throughout the State, and the creation of the office of State Engineer, it was recognized that many advantages would come through having the administration centered, if possible, under one single authority.

To effect this a statute was passed giving the State Engineer authority, in his discretion, to establish water districts and appoint water commissioners to distribute the waters. There followed, as might be expected, a conflict between the jurisdiction and authority of the Courts and that of the State Engineer in the administration of water rights. This controversy was decided by the Supreme Court of Utah in favor of the State Engineer, who was held to have administrative charge of the distribution of water in the State and who, therefore, could, where the proper formalities had been complied with, supersede the Court Commissioner by one of his own appointment.

Along with this gradual development there grew up the most important theory that the determination of the rights was solely a matter for the Courts, and that the administration of these rights was in the hands of the State Engineer. This division and separation of authority is thoroughly sound and of great practical value in avoiding the overlapping of functions which must always produce confusion.

One of the chief administrative difficulties in Utah arises from the fact that water rights are of two distinct origins. The older rights are the result of appropriation merely by beneficial use and, in a great many cases, are not of record anywhere. Where these rights have been the subject of litigation there followed a Court decree, but these Court decrees are very seldom definite, and some of the older ones are so faulty that they prevent any intelligent distribution of the water according to their terms.

In 1903 the law was passed requiring application to the State Engineer as an essential for the acquirement of right to unappropriated water in Utah. After the passage of this law an additional complication arose, owing to the

\* State Engr., Salt Lake City, Utah.

fact that a few water users scattered over the State, either knowingly or ignorantly, ignored this law and attempted to acquire rights merely by the diversion of water to beneficial use. This situation existed for more than twenty years, until it was finally cleared up by a decision of the Supreme Court of Utah in 1925, which held that no water right initiated subsequent to 1903 was valid unless acquired through application to the office of the State Engineer.

It is obvious that a full and complete record of water rights initiated subsequent to 1903 exists in the office of the State Engineer; but as to the rights acquired prior to 1903 the record, if any, is scattered through the files of the various District Courts in the form of decrees. A beginning of remedying this unsatisfactory condition was made by the passage of a law in 1919 prescribing a method of adjudicating water rights through co-operation with the office of the State Engineer. In the earlier litigation there was always a great mass of conflicting testimony and no impartial study or investigation of any sort.

The new law is most valuable in that it provides for this impartial study and investigation by the State Engineer's office with a definite recommendation to the Court in the form of a proposed determination as to what, in the judgment of the State Engineer, the rights should be. Ample protection to the water users is secured by a provision that each must be served with a copy of this determination, and that any water user may object to the right proposed for him and have his day in Court to present such evidence as he may desire, showing the incorrectness of the right proposed.

Considerable progress in adjudicating rights has been made under the new law which has proved very satisfactory to the water users in its technical results, and also, in that its cost is but a fraction of the cost of litigation under the old method.

Real success of the administration of water rights is dependent wholly on an exact description and definition of such right. In the various districts where adjudications have taken place under the law of 1919 this information is available, being equally at the disposal of the water commissioner and of the various water users, with the result that the matter is wholly in the open and each user knows just what his neighbor's rights are. This makes for the essential understanding which is necessary for co-operation between all concerned and the old differences and frictions are practically eliminated.

In the older districts where the rights are less clearly defined there are complications not only of proper physical distribution but of the assessment of its cost as well. Continued efforts are necessary to educate the water users in such districts as to the difference between an actual right and the quantity of water available to supply such right.

With practically no exception all the water sources in Utah are heavily over-appropriated, which means that the problem of distribution is entirely different in a dry year from that in a wet year. In a dry year the later appropriations must have their supply cut out as the season of high water draws to an end, and this means that all rights are not of equal value.

Therefore, for the purpose of assessment, the rights are frequently divided into two or three classes and the levy per acre is made considerably less in the case of those rights that fail of supply at the end of the high-water season.

While the fundamental law of water rights, "first in time first in right", is in general controlling, there are a number of exceptions in a dry season. Besides this fundamental law is a secondary division according to use, into domestic, irrigation, power, and miscellaneous rights. The laws of Utah imply that the matter of priority does not necessarily run to the extent of withholding a junior domestic right to supply a senior irrigation right, or a junior irrigation right to supply a senior miscellaneous right. An added complication is found in many of the older Court decrees where the dates or priority were uncertain of record and the Court in its decree divided rights into classes. Where this situation exists it is also usual to deviate from the classes to take into consideration the secondary priority as already outlined.

It is possible that with future developments some method may be found of doing away with the classification in these old Court decrees, at least to the extent of having one fixed early date covering the unknown and uncertain priorities and, after this, definite dates for the other rights. At the time the Utah adjudication law of 1919 was passed there did not seem to be sufficient progressive sentiment to write into it a provision which reviewed in whole these old Court decrees and substituted for their provisions the modern and latest description of water rights. In formulating the State Engineer's proposed determination, it is necessary to follow quite closely the terms of the Court decrees, except where these in actual practice have been found by the irrigators to be so unsatisfactory that they are glad to have them changed.

There is another extremely important phase of administration which can only be mentioned. This has to do with the administration of such water rights as are of record ownership in some agency of the Federal Government. Two types of this situation are the distribution of waters owned by the United States Indian Service or its successors in interest, and water rights and lands embraced in Federal Reclamation Projects. At present (1927), there is not the slightest attempt on the part of the State to take over the Federal control of distribution any more than there is active effort by the State Engineer to supersede by his commissioners the various Court commissioners still distributing water on numerous streams in the State. On the other hand, no good can come, either of division of authority or indefiniteness of such authority. In view of the accepted theory that States control water rights and of the tendency, observed from time to time, toward centralization under Federal control, a definite policy must be pursued by States in the arid region with reference to retaining these particular rights which have been regarded as definitely settled by decision of the United States Supreme Court in favor of the State. If attempts to view this matter as not finally settled are ignored, there is always the possibility that the question might be re-opened and under circumstances which, in the future, might cause the loss of valuable rights.

It is hoped that the foregoing brief review has indicated a plain tendency for administration of water rights to approach closely the ideal state expressed by the following controlling conditions

(a) Complete separation and definition of powers affecting water rights; one body, namely the Courts, to determine the rights; and the administration and distribution of these rights by another agency, the State Engineer.

(b) The abolition of all Court Commissioners, their places to be taken by commissioners appointed by the State Engineer, after consultation with the water users.

(c) A method of assessments based strictly on water rights with such adjustment as will make them agree approximately with the value of the right in terms of available supply.

## DISCUSSION

---

M. C. HINDERLIDER,\* M. Am. Soc. C. E.—Unquestionably the greatest resource of the arid States of America is their water supplies, and hence the administration problems in this connection are of profound interest to the people of these States. The officials charged with the administration of the Court decrees relating to water supplies, are confronted with many intricate, illusive, and difficult problems.

The laws of most of the arid States relating to the administration of water supplies, lay down broad, comprehensive rules applicable in general to the entire State. Due to the variable character of stream flow, climatic conditions, and the diversity of use of the waters, many conflicts have occurred in the past and others continue to arise to aggravate and confound the officials. Although, in general, these laws have been interpreted by the Supreme Courts of the various States, there are many shadings in such opinions which of necessity leave to an administrative official many intricate questions on which he must pass in administering the duties of his office.

Colorado, next to California, has the largest area of land under irrigation, and has by far the most extensive system of reservoirs and canals. For the most efficient and economical use of her available water supplies, it has been found needful to provide for a comprehensive system of administration which involves the storage of water in reservoirs located both on the channels of natural streams and at points sometimes far removed from such streams; and for a system of exchange between ditches, reservoirs, and the streams.

The Constitution of the State of Colorado provides that priority as to time of use shall constitute the better right as between those taking water for a like purpose. Furthermore, it is stipulated that the right to divert water from any natural stream for a beneficial use, shall never be denied. No limitation whatsoever is placed on any one who appropriates water on any stream, except that of priority of original use and beneficial application.

Colorado has substantially 1 000 storage reservoirs, in which a large proportion of the available water supplies are stored in times of plenty for use in times of shortage. In order that it may be made available to the various canals and ditches, the law provides that water may be released from reservoirs and transmitted down natural streams and taken out again by the water owners, all under the supervision of the State water officials. This one phase alone involves one of the most difficult and illusive problems with which administrative officials are confronted.

The law provides that the same quantity of water released from a reservoir on a stream above, may be diverted by a canal below, minus a certain quantity for loss in transit to be determined by the State Engineer. This loss varies greatly from time to time, depending on the distance between the reservoir and the canal taking the water; the stage of the river and the quantity of water released by the reservoir; the climatic conditions which may prevail at the time such water is being released from the reservoir; the char-

\* State Engr. of Colorado, Denver, Colo.

acter of the stream channel, etc. Probably one of the major factors affecting such deliveries is the control of the head-gates of ditches along the stream during such runs of water.

The water officials in Colorado have made many attempts to determine the probable loss of reservoir water in transit under changing conditions, and have found that, due to the variable nature of the many factors involved, it is possible only to ascertain the amount of the losses within certain limits. Such experiments have shown that these losses of water in transit vary from 2 or 3 up to 30% of the water released from a reservoir.

For a proper accounting of all the water supplies in Colorado, the law provides that every reservoir shall be carefully contoured to determine the capacity thereof; and that the reservoirs must be equipped with proper gauge rods, marked in feet and tenths of feet, to indicate the depth of storage therein at any time; that proper measuring flumes or other devices equipped with automatic registers, shall be installed on all streams flowing into the reservoirs and also on all outlets.

The quantity of water in storage at the end of each month in all the major reservoirs is reported to the principal administrative official for that division. While Colorado laws do not divide the calendar year into seasons for direct irrigation and for storage of water, climatic conditions practically effect the same result; that is, when water ceases to be needed for direct application to the land for irrigation, the reservoirs are permitted to store water in order of priority.

When stored water is required by owners along the various streams, it is released from the reservoirs under supervision of the local water officials, measured over automatic registers, and a similar quantity of water delivered to the head of the canal below, minus a certain quantity which is deducted for loss in transit.

Assuming that all head-gates located on the stream between the reservoir and the point of delivery are properly regulated and controlled to insure that other owners do not divert water to which they are not entitled, the only material loss in transit is occasioned by evaporation.

It is true that under certain peculiar conditions loss of water from a stream occurs through subterranean channels which may lead to lower areas adjacent to a stream, but such losses are rather infrequent except for short stretches along a stream.

Some time ago the speaker conceived the idea of attempting to compute evaporative losses from stream channels by first ascertaining the exposed surface area of the channel at different stages of flow, and then applying the proper evaporation coefficient applicable for any particular day. It was soon discovered, however, that the stage of the stream varied radically both day and night, especially in shallow streams with sandy beds and numerous sand-bars. This made it impossible to determine with any reasonable degree of accuracy the probable surface area exposed to the air and sun at any time.

As a means of securing more efficient administration of reservoir runs, it was found needful to exercise the most painstaking supervision over the

head-gates along the river between the points in transit. To effect such administration it was necessary to require that automatic registers and accurate measuring devices be installed in the ditches. With such equipment supervised by the local water commissioners and their deputies, it has been found that many of the old problems affecting the transmission of reservoir water have been successfully met.

There are eight requisites for a proper and efficient administration of both canal and reservoir decrees and for the transit of reservoir water along a natural stream. These may be listed as follows:

*First.*—Proper head-gates in all ditches heading on the stream, with facilities for locking them down if necessary.

*Second.*—Proper measuring devices equipped with automatic registers for determining the quantity of water diverted hourly by the various ditches.

*Third.*—Numerous gauging stations equipped with automatic registers placed along the stream at strategic locations.

*Fourth.*—An efficient corps of experienced hydrographers to rate the gauging stations and canals and patrol the river during reservoir runs.

*Fifth.*—Conscientious water commissioners and deputies to patrol the stream and the head-gates of all canals to see that the water is distributed strictly in accordance with order of priority.

*Sixth.*—A proper system of telephone communication between the reservoirs, the river stations, all canal head-gates, and the chief administrative official.

*Seventh.*—A proper system of daily reports between the local water officials and the chief administrative official, showing the quantity of water (both morning and evening) available for distribution; the quantity of water diverted by each head-gate; the quantity of water stored in each reservoir, and in transit down the stream for any ditch.

*Eighth.*—A proper register of the Court decrees showing the order of priority in which waters may be diverted or stored, and a thorough understanding of these decrees by the administrative officials.

As a further material aid in the administration of reservoir runs and other water decrees, State officials have found that a diffusion of the knowledge of what occurs on the stream each day, or possibly more frequently, by means of a bulletin issued by the chief administrative official or secretary of the ditch organizations along the stream, is most beneficial.

They have found that a complete knowledge of water supply demands and distribution, if made available to the water user, dissipates suspicion, removes grounds for complaint against the administrative official, and provides a permanent record for future reference, which is invaluable.

As time passes and water supplies become more valuable and require a more careful supervision and greater efforts toward conservation, greater efficiency will be demanded, which will inevitably result in improved methods of measurement, control, and accounting.

Mention has been made of gains to the river resulting from the transit of reservoir water along a stream. There can be no actual gain or accretion

in the total available water supply as a result of such reservoir runs, but, on the contrary, there must always result some loss of the water in question, due to evaporation and, possibly, to deep percolation away from the stream channel.

It is true, however, that following these reservoir runs, the stream frequently benefits because of the return flow of percolating waters draining out of the sand-bars and land adjacent to the stream channel.

If the percentage of assumed losses chargeable against the reservoir is excessive, the reservoir run suffers. If on the other hand the estimated percentage for loss of water in transit is not sufficiently high, the other rights along the stream suffer.

After releasing water from a reservoir farther up on a stream, and turning an equivalent quantity of water out of the river into the head-gate of the receiving ditch, it frequently happens that some other canal immediately below, which up to that time had been securing its full quota of water, is deprived of all, or some portion, of the water theretofore drawn.

Unless there has been a material change in climatic conditions affecting the natural stream flow, it is obvious that the reservoir run has not been sufficiently penalized, with the result that great injury is done some water user along the river. Since the values of these water supplies are measured daily in dollars and cents, the effect of poor administration has all the results of depriving an owner of actual property with all the resultant dangers of ill-feeling, litigation, property losses, etc.

From the foregoing it may be observed that the intricacies involved in the administration of the water supplies in the Western States and a proper solution of the problems, challenges the earnest and intelligent effort of the administrative official, the best statesmanship of legislative bodies, and the most painstaking thought of the Courts.

R. I. MEEKER,\* M. AM. SOC. C. E. (by letter).—Mr. Baldwin has tersely presented his administrative experience dealing with transmission losses incident to runs of several thousand second-feet of reservoir water for stretches of several hundred miles in a large river, in which channel conditions as to gains and losses are variable and administrative problems are complex.

The history of river administration should record an evolution in charges imposed on reservoir water conveyed in river channels. Realization on the part of water users and water officials that there are wide fluctuations in river gains and losses due to stream-bed formations, return flow from irrigation, and other causes, will go a long way toward securing the necessary funds to make engineering studies with which to guide administrative practice.

Continued engineering measurements of river channel flows for gains and losses are necessary in order to fit administration practice to conditions of natural fluctuating river stages, to conform to changing river conditions in irrigated valleys, and to eliminate conjectures and prejudicial assertions frequently made by opposing parties in such matters. Channel losses or gains in a river system may be far different to-day than those of the past or the future. They also vary with the size and compactness of adjacent irrigated areas.

\* Cons. Engr., Denver, Colo.

By statutory enactment in 1879, conveyance of reservoir water in river channels in Colorado was made subject to deduction for evaporation and seepage losses. Subsequent legislative acts in 1897 imposed a "reasonable deduction for seepage and evaporation" on waters transferred from one stream to another, or on exchanges of reservoir and ditch water. The State Engineer was designated as the agency to make determinations of losses applicable to such waters.

In framing legislation concerning conveyance losses of reservoir water, inter-water-shed diversions, and exchanges of water, the underlying principle has been "the non-injury to other water rights upon a stream system." In administrative practice, reasonable doubt, therefore, has usually been resolved against the reservoir water.

Notwithstanding engineering information on river channel losses, the question of penalty losses applicable to reservoir waters transferred in river channels is fertile ground for water disputes, especially in dry years when the effect of water shortage is felt. The writer's experience on losses applicable to reservoir water in transit in river channels convinces him that frequently grounds for complaint by direct-flow users are justified. Actual losses sustained by prior users sometimes occur from weak administration of intervening diversions, in river sections between the reservoir and the diversion works, rather than from actual channel losses by seepage. Evaporation losses of water in transit usually are negligible when compared to percolation or administrative losses. Seepage and administrative losses are frequently confused.

TABLE 2.—TRANSMISSION LOSSES IMPOSED ON RESERVOIR WATER.

Reservoir.	Stream.	River channel distance, in miles.	Character of river bed.	Deduction, percentage.	Basis of determination.
Twin Lakes....	Arkansas.....	160	Chiefly through mountains.	10	By stipulation; engineering studies under way.
Rio Grande....	Rio Grande....	80	Through mountains.	8	By stipulation.
Antero.....	South Platte ..	100	Through mountains.	12.5	Stipulation modified by engineering studies.
Cheesman .....	South Platte ..	25	Through mountains.	2.5	By stipulation and stream-flow records.
Cheesman .....	South Platte ..	55	Through mountains and plains.	5	By stipulation and stream-flow records.

In mountainous country, channel percolation losses are usually quite small. In plains and valley sections of rivers, both seepage and administrative losses may be heavy. River channels through lava (basalt formations) are likely to be erratic as to losses or gains, and should be evaluated by actual measurements. As river channel losses are seldom directly comparable, the application of percentage deductions for one river section to other river sections, or from one river channel to another, is dangerous.

On account of lack of funds for engineering studies in advance of reservoir runs, transmission losses applicable to "reservoir runs" generally have been

set by stipulation of the interested parties and water officials, and, later, have been checked by engineering measurements and modified in accordance therewith. The time has come for engineers, water users, and administrative heads to insist on funds for investigating these matters. The loose haphazard methods of the past concerning penalty losses applicable to reservoir and interstream waters should be relegated to oblivion. Problems of dwindling water supplies, increasing use of stored waters, and changing river conditions due to irrigation, power, and industrial uses, demand engineering treatment.

Table 2 outlines roughly the transmission losses charged against reservoir water in Colorado. The data therein contained are taken from records of the State Engineer's Office at Denver.

LYNN CRANDALL,\* M. Am. Soc. C. E. (by letter).—The construction and operation of storage reservoirs on natural stream channels in the irrigated areas of the Western United States have resulted in more or less contention between the owners of the stored water and the owners of earlier natural flow rights. The disputes thus occasioned generally pertain: First, to the segregation of stored water and the natural flow as discharged from the reservoir; and, second, to the proper transmission loss to be charged to stored water while in transit in the stream channel between the reservoir and the place of diversion from the stream.

The practice of determining the daily amount of storage released, from reservoir drop and capacity tables, as used at Jackson Lake and Henrys Lake Reservoirs and elsewhere, is probably the simplest method to apply. In all cases it is useful as a check on other methods, but its application causes all errors and fluctuations from erroneous capacity tables, evaporation losses, return ground storage, etc., to be thrown into the determined daily natural flow. This, in turn, causes fluctuations in the determined natural flow from day to day that would not exist except for the construction and operation of the reservoir and the use of this method of segregating the stored water from the natural flow. While such fluctuations may balance throughout the season, the natural flow rights are often of varying dates of priority, and during periods when the stream flow is not sufficient to fill all the natural flow rights, this method may deprive certain of such rights of water, to the advantage (at some other time during the season) of other natural flow rights of different dates of priority. For example, in various reservoirs with which the writer is familiar the water held as ground storage amounts to from 3 to 10% of the open reservoir storage as determined from the contour surveys, and during the course of the season this may compensate fully for evaporation losses. However, such losses are generally greatest when the reservoir is full, while the return from reservoir ground storage usually reaches a maximum later in the season when the reservoir is being lowered rapidly. Under this method of operation, then, the evaporation loss may cause a certain natural flow right of late priority to be cut off earlier than it should be, while the ground storage gain accrues to an earlier right still being filled later in the season. On reservoirs with numerous fluctuating sources of supply, however, this method is

\* Water Commr., Big Lost River, Idaho Falls, Idaho.

about the only practical one, but in such cases its use should be supplemented by special investigations like those made at Jackson Lake. Records of all inflow, outflow, evaporation, ground-water fluctuations, etc., should be secured so as to afford a basis of evaluating the effect of operation on any particular rights involved, as well as a means for calculating a reservoir capacity table, based on inflow and outflow records, independent of that determined from contour surveys.

Where there is no natural gain to the stream in the reservoir site, or where such gain, if any exists, comes from springs that are fairly uniform in flow, it will usually be found more satisfactory, fairer to every one concerned, and less productive of dispute, to determine the reservoir inflow each day from a gauging station, or from stations situated above the back-water of the reservoir. Then add to or subtract from such inflow an agreed or determined flow for natural gain or loss in the original stream channel through the reservoir, thus securing the natural flow passing the gauging station below the reservoir, any surplus at that point, over such determined natural flow, being deemed released stored water. This method is prescribed in the Court decree governing the distribution of the waters from Big Lost River, Idaho. An allowance of 34 sec.-ft. is made for natural stream gain in the Mackay Reservoir, which is based on records compiled during periods when the reservoir was empty. A similar method is followed in the operation of the Magic Reservoir on Big Wood River, Idaho. On Big Lost River, it has been found necessary to locate the measuring station at least 2 miles below the dam, in order to get far enough down stream to intercept all the ground-water outflow from the reservoir, more than 100 sec.-ft. of which flows around or under the dam itself when the reservoir is full. Even in the case of reservoirs with a large inflow from springs (provided records are available prior to the reservoir construction or during periods when it was empty), it may be more satisfactory and equitable to determine or agree on a figure, to represent such natural gain through the reservoir site. If the records justify it, a slightly different figure should be used for different times during the season, rather than rely upon some method which might result in unwarranted fluctuations being caused in the calculated natural flow.

Having segregated, by some means or other, stored water from natural flow as it leaves the reservoir, the question of proper transmission loss to charge stored water as it flows in the natural channel, mingled with natural flow, to the point of diversion from the stream, still remains as a source of contention. In this case, as in the case of segregation of water at the reservoir outlet, it would seem fair to start with the basic assumption that the natural flow rights are entitled to the quantity of water that would be available at their points of diversion if the reservoir had never been built or if stored water had never been carried in the stream, and that any additional amount available over and above such quantity belongs to the owners of the stored water.

The loss occasioned by running stored water in natural stream channels will vary widely, depending on whether the stream naturally loses or gains water in the section considered. The head-water areas of most Western streams are regions of fairly heavy precipitation, where the stream gains from tributary

ground-water inflow. As the stream emerges from the mountain canyons into the lower valley, it often flows for some distance over a delta or cone where the adjacent ground-water level is lower than the water level in the stream, and where the natural channel loses water at all stages. Farther down stream the ground-water may again rise higher than the water level in the stream, resulting in a ground-water inflow, and it may then gain to the stream in such sections. On numerous Western streams such alternate sections of gain and loss occur for many miles.

In sections where the stream loses water due to the adjacent water-table being lower than the level in the stream, the stored water should manifestly be charged with the additional loss created by carrying it, as compared with what the natural loss would be without including the stored water. The practice of determining percentage losses in the channel with both stored water and natural flow in the stream, while supplying information of interest, should not be relied on entirely to determine proper losses chargeable to stored water. A comparison of losses with natural flow alone, and when carrying the additional stored water should also be made. Studies of the ground-water flow through the valley must necessarily be made to determine whether the water lost in the "loss" sections of the stream returns farther down stream as gain and, if so, when and where such return takes place. Stored water is properly entitled to credit for whatever portion of the "lost" stored water that returns to the stream above diversion points during the period of full use of the stream flow each year. In some of the larger river valleys of the West, this "lost" water requires several years to complete its underground travels and finally emerges as ground-water or spring inflow into the stream. Thus, the continual carrying of stored water for year after year may result in that portion of such stored water that is lost in the "loss" sections, finally re-appearing as a permanent increase in the gain to the stream in the "gain" sections.

In sections of the stream where the water-table is higher than the water level in the stream channel, the stored water sustains little actual loss, but it has the effect, when first turned in, of damming back part of the natural ground-water inflow until the ground-water slopes adjacent to the stream re-adjust themselves to the higher water level in the stream occasioned by the stored water. The effect of running stored water in such sections of natural gain from ground-water inflow to the stream can best be studied by noting the reduced gain for a short period, varying under different conditions from a few days to several weeks, when stored water is first turned into the channel. This temporary bank storage returns rapidly to the stream when the stored-water run ceases and the stream drops to its natural level. In the delivery of stored water on Big Lost River, the matter is adjusted by allowing the natural flow rights to use some of the stored water during the first week that it is turned into the stream, the same quantity being repaid to the stored-water owners later in the season from the increased gain that occurs for a brief period when the stored-water run ceases.

As pointed out by Mr. Baldwin, the matter of the equitable segregation of stored water and natural flow is a complicated one in many cases. It is not subject to exact determination on account of differences in climatological

factors, ground-water levels, stream channel conditions, etc., from year to year and at different times during the same year. By securing records covering a number of years on inflow, diversions, and losses along the stream, together with studies of the ground-water movements, however, a basis may be developed for an intelligent study of the question, and a fair approximation may be thus reached for the determination of the natural flow and stored water, as each is delivered to its respective owners.

THOMAS R. NEWELL,\* Assoc. M. Am. Soc. C. E. (by letter).—An outline of the methods used in transmitting and delivering reservoir water in Water District No. 36, Idaho, has been presented by Mr. Baldwin. It is mentioned that transmission is effected through the Snake River channel from both the Jackson Lake and American Falls Reservoirs to the river head-gates of the numerous owners of storage rights. Thus, the channel of the main river carries an increment of reservoir in addition to the current run-off of the water-shed during a large part of the irrigation season. Natural water distribution must be made simultaneously with storage delivery despite the complications introduced by mingling this current run-off with these continuous streams of transit storage. In some sections of the river the reservoir water increment is even greater than the natural flow during part of the season. The relative proportions vary for years of differing snow supplies and irrigation demands.

Transmission loss schedules and reservoir outlet divisions always must meet the tests of changing conditions and even of changing ownerships. The small percentage of ultimate wastage (flow past Milner Dam during regulation period) is a real index of the excellence and efficiency of the control system of river operation as a whole. The fact that these major reservoirs have been operated ever since their construction in conjunction with natural water distribution from the same water-shed, through identical delivery channels and without the authority of a Court Commissioner, speaks well for the efforts of the administrative official and perhaps also for the tolerance of district water users.

The compromise agreements upon which division is made between natural and reservoir waters when flowing commingled are of particular interest to the writer. In Water District No. 36 these agreements consist of brief digests of methods of division at reservoir outlets and schedules of percentage transmission losses to be applied through successive river sections to transit storage. As they are adopted annually in slightly revised form, these compromise schedules should carry greater prestige from year to year, and as time goes on, should become more nearly representative of true conditions. It is readily seen that variations in these schedules directly affect the quantity of reservoir delivery. In like manner, changes affect the total supply of natural water in the opposite direction. Even now basic changes are stubbornly contested and are almost impossible of adoption without recourse to hydrological investigations of a co-operative nature. Objections of merit are usually met by secondary arrangements or the granting of special privileges to avoid upsetting standard compromise schedules.

\* Care, U. S. Geological Survey, Boise, Idaho.

In this connection it is interesting to note the exact effect of a change in a river operation agreement from the viewpoint of a holder of a natural water decree and a user of reservoir water. Assume, for example, that a transmission loss schedule is increased 10 per cent. Each storage owner's holdings are decreased 10 per cent. The only escape he has from the penalty is that his storage right may be a mere insurance and seldom withdrawn. This same increase in applied transmission loss increases the total supply of natural water, but not *pro rata* to each holder of a decreed right. In Idaho, a decreed right specifies a quantity (if beneficially used) and, in all cases, a priority date. As river supplies decrease below the quantity necessary to fulfill all decrees in use, the river water master refers to his chronological list of priority dates and declares that right with the latest date either partly or completely invalid and denies use thereunder. This process of eliminating one user after another is continued until the river stage reaches the summer low. Then, as supplies increase, each decree is restored in reverse order.

Pioneer rights to the extent of the minimum summer flow remain untouched and, in reality, have no interest in the changed transmission loss. The younger the right the longer is the period of denied use which must be suffered. To each invalidated right an increased transmission loss means an extended time of validity at either end of its period of denied use. The length of the extension is defined by the amount of gain to natural supplies due to the changed schedule and the rate of river decline or increase. It may not encompass the whole decree and it may not help for more than a single day; but for several years the storage delivery rate from the Jackson Lake Reservoir has been quite large during the months of July and August. Likewise, the summer minimum of Snake River flow usually remains fairly constant for several weeks in the height of the irrigation season. Therefore, it is possible for a single large decree, properly placed along the chronological scale, to garner a lion's share of the total increase in natural supplies resulting from a changed transmission loss.

To carry the illustration still further, it is true that many of these young rights have purchased supplemental storage, so that their gains may be partly offset by losses to their supplemental supplies. Careful study of these effects serves to accent the fallacy of the popular belief that any general method of division between the two classes which balances for the season is fair to the individual decree holder. It may also present to the politically minded an interesting angle of the "ins and outs" of stipulative agreements.

Compromise river and reservoir agreements should tend toward workable methods of division which should be fair to each party throughout each season and which should keep pace with current events. With the initial draft from the new American Falls Reservoir comes a series of changed ownerships, new river complications, and notable variations in river regimen extending from Jackson Lake all the way to Milner. A reservoir outlet division, operated on the contour method, in which evaporation losses and natural storage credits are balanced against bank storage return, usually contemplates a full use of the reservoir and cannot be expected to serve a hold-over storage unit. Henrys Lake Reservoir is notably in the latter class and on account of recent

changes in ownership at Jackson Lake, this great storage unit is tending in that direction.

These same factors operate toward less regular increments of reservoir water being carried through the main river channel. Flat percentage rates of transmission loss and flat time interval allowances for any and all river stages and rates of delivery will not so fairly comprehend the new situation. Lag credits help to even the charges, but should be applied in direct proportion to increases in stage and should not be permitted to be used in any but a regular mechanical manner. The space privilege, the temporary transfer, and many permanent transfers might each serve an honest purpose did they not so often go hand in hand with appropriation and even Court decree beyond the bounds of beneficial use. The current dearth of water supply in Water District No. 36, due to the many new storage purchases (made possible by the construction of the American Falls Reservoir, and the ample natural run-off of 1927 and 1928), has eased the river operation situation temporarily. The advent of a season of shortage will not soon bring general crop losses on account of the presence in the district reservoirs of much "water insurance" which may be rented; but with the reclamation of additional lands, now contemplated, supplies will eventually be depleted to the point where river and reservoir problems will become more important.

Only a part of the transmission and division agreements now in force have support in actual seepage investigations. Of these investigations, many have been continued during one season only, while some are based only on miscellaneous field runs. Continuity through different types of seasons—the fundamental of every thorough hydrological study—has been denied in most cases. Few, if any of the channel studies made in the past, show the application of the modern methods of refining river-station differences in use in California and some even ignore surface tributary inflow as an independent variable. The Kootenai River study now in progress (1928) on the International Boundary has been planned with a view to obtaining a degree of refinement far beyond that of any lake or reservoir segregation yet made in this district. The criticism often heard, to the effect that the segregation of the many factors involved can never be exact, is true despite the use of the most modern methods economically feasible.

However, real values do result from orderly presentation of measurable factors properly qualified as to exactitude. Just divisions require careful observation of seasonal trends of disputed factors. Developed waters resulting from drainage recoveries, return flows from new irrigation, artificial ground storage, and reservoir bank storage, should each be observed currently. Changed plans for reservoir drafts due to changing ownerships should not be overlooked. All in all, too much should not be expected of old and insufficient investigations, and every effort should be made to make the new ones more thorough and continuous. The effort to centralize and co-ordinate all administrative activities, within the district, has built up a continuing and an adequate organization which has effected improved operation service. The basic schedules underlying operation schedules are entitled to equal consideration and support.

To the student of river operation, Mr. Baldwin's paper is particularly interesting, in that it is representative of ten years' experience in transmitting reservoir waters at rates of much greater magnitude than usual. The same rules which apply to storage deliveries at the rate of a few miner's inches for a few miles are entirely inadequate in transmitting reservoir water by the thousands of second-feet for hundreds of miles to the respective owners. It is to be regretted that more detail has not been included for a careful description of the very effective system of control which has resulted in uninterrupted service and, at the same time, a negligible ultimate waste. The attainment of these two ends is the mark of good regulation and deserves the careful consideration of every person interested in orderly distribution on a large scale.

E. B. DEBLER,\* M. AM. Soc. C. E.—The State of California adopted riparian rights as the basis of its water rights many years ago, and as no affirmative action on the part of the grantee was required, such rights became vested as to all riparian lands, with the action of the State Legislature.

Fundamentally, riparian rights imply non-consumptive uses only, but in the main the Courts have upheld any uses which did not deprive other riparian owners of their proportionate share of such use.

Recent attempts to impose limitations on the use of these riparian rights, even if only in support of a more efficient use of the State's water resources, either by legislative enactment or by regulations of an administrative arm of the State Government, are likely to prove fruitless as they would appear to be in the nature of confiscation of a vested property right which the Courts will not sanction. In view of this situation, plans for the conservation of the water resources of the State must be placed on a sounder legal basis.

The situation with regard to conflict of riparian and appropriation rights is not limited to California. Both types of rights exist in a number of Western States. Nebraska has adopted riparian rights for its humid section and appropriation rights for its arid section. Land grants by the Spanish Crown in the Southern Border States often carried water rights, sometimes distinctly "appropriation" in character, at other times, "riparian." The outcome of California's attempts to curb riparian rights will be watched with interest, as it is likely to be followed in after years by similar attempts in other States when water becomes of greater value.

G. CLYDE BALDWIN,† M. AM. Soc. C. E. (by letter).—Discussion of the writer's paper has very properly not been limited to the problems incident to the transmission and delivery of water from Snake River reservoirs. Mr. Hinderlider has presented an excellent summary of the methods used in the State of Colorado and has listed eight so-called requisites for equitable and efficient water administration which, with possibly slight modification, should be generally applicable.

The extent to which transmission losses are increased by "adverse-user" diversions, together with the accessibility of their head-gates, obviously will

\* Engr., U. S. Bureau of Reclamation, Denver, Colo.

† Hydr. Engr., U. S. Geological Survey, Idaho Falls, Idaho.

determine the degree of regulation which should be enforced. For example, it would probably be unwise to attempt to prevent the use of water by isolated canyon ranches unless the resulting benefits to be derived by the owners of older rights would be sufficient to justify the expense of the regulation.

Mr. Meeker emphasizes the desirability of continued, comprehensive, engineering investigations and reports as an aid to better administration, and this is also stressed by Mr. Newell. Both, however, recognize the variable, complex character of the different factors on which the stream flow at any given point depends, and they understand that exact solutions of river or reservoir loss problems can never be attained.

Engineers usually are anxious to secure an increasing amount of data on such subjects in order to minimize the always recognizable error in the final application.

From the practical viewpoint of the ordinary water user, on the other hand, extreme accuracy seems less essential, especially if the engineering investigations must be done at his expense. Furthermore, in such extremely complicated problems as those on Snake River, the same basic facts may be used sometimes in good faith by different engineers to derive somewhat divergent conclusions. The water users, therefore, as a group, are rather slow to adopt radical changes in methods of operation and prefer to follow the usage of preceding years, with perhaps slight modifications based on new facts, rather than to sanction expenditures for engineering investigations which may result in controversy.

As mentioned by Mr. Crandall, segregation of stored water and normal stream flow at the outlets of reservoirs and the schedule of losses to be charged the former while in transit in the stream channel between the reservoirs and points of diversion are usually the two principal sources of contention in river administration.

The desirability of having these points settled by Court order or decree has long been recognized by those most interested in the storage and delivery of water on Snake River, and much has been accomplished through special studies and investigations with that end in view. At present (January, 1929), reports covering ground-water conditions along Snake River and the 1928 gains and losses in the American Falls Reservoir Basin are in process of preparation.

The net result of more than ten years of river operation has been the plan described in the paper which, as modified from time to time to meet new conditions or to be more consistent with added facts as they became available, has now, through precedent, attained a position almost comparable to, and may eventually be converted into, a Court order through stipulation by the interested parties.

Drainage Recovery from Irrigation	
By D. W. MURPHY, M. Am. Soc. C. E.....	333

WITH DISCUSSION BY MESSRS. R. I. MEEKER AND FRED H. TIBBETTS.

\* Presented at the meeting of the Irrigation Division at Denver, Colo., July 14, 1927.

## RETURN WATER, NORTH PLATTE RIVER, NEBRASKA

By R. H. WILLIS,\* Esq.

## SYNOPSIS

The subject of return water is an interesting problem in the North Platte Basin. To determine, with a reasonable degree of accuracy, the quantity of return water in any irrigated area it is necessary that full co-operation be maintained between the State Department and the managers of those projects diverting water from the stream. Experience shows that it takes several years to obtain the necessary co-operation from project managers. In Nebraska, it has not yet been fully attained.

## QUANTITIES

The quantity of water returning to the North Platte River, after being diverted for irrigation, is amazing to those who have not observed the habits of this stream. The mean annual flow since about 1900, at North Platte, Nebr., is 2 294 000 acre-ft. This mean is not likely to change materially by having more years of record. Approximately, 1 200 000 acre-ft. have been diverted from the stream during each of the seasons of 1925, 1926, and 1927, between Whalen, Wyo., and Bridgeport, Nebr., and were conducted to the farming lands in the basin. About 65% of this water came back to the stream. This water is known as "return water", "return flow", "seepage", and "unused water."

In 1909, there were probably fewer than 50 000 acres under irrigation in the valley west of Bridgeport. Not until 1912 did the visible return flow become perceptible. After 1909 much additional land was put under irrigation between Whalen and Bridgeport. By 1919 the total had reached 233 000 acres. At present, (1927), the irrigated area in the valley comprises approximately 350 000 acres.

## ELEMENTS CONTRIBUTING TO RETURN FLOW

Since 1910 there have been two main factors affecting the habit of the river, namely, the storage of flood water in the Pathfinder Reservoir, and the increased diversions from the stream. The reservoir serves as a direct retard of the flow of the stream from the non-irrigation to the irrigation season. The effects which flood storage and return flow have on the lower section of the North Platte River are shown graphically in Fig. 1. The mean monthly flow before and after the completion of the Pathfinder Reservoir is shown for each month of the year. It will be noted that since the construction of the reservoir the mean flow for May and June has been approximately 50% less than the mean prior to that time. For July, the mean flow has been

\* Chf., Bureau of Irrig., Water Power, and Drainage, State Dept. of Public Works. Bridgeport, Nebr.

30% less; for August, 95% more; for September, about 225% more; and for October, 215% more than the mean flow prior to the beginning of storage in the Pathfinder Reservoir. This increased flow during the months cited is the result of the application of water to the irrigated area between Whalen and North Platte.

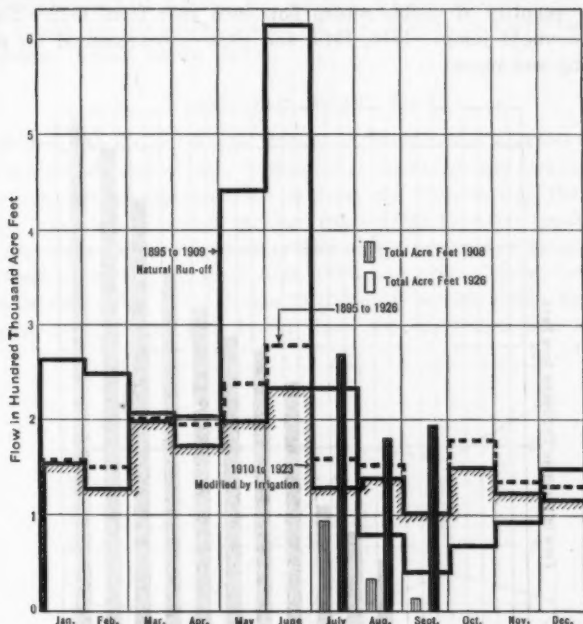

FIG. 1.—MEAN MONTHLY DISCHARGE OF NORTH PLATTE RIVER, AT NORTH PLATTE, NEBR.

The increased diversion of irrigation water has been the major contribution to the return flow. It is generally admitted that approximately 1 sec.-ft. of water is consumed for every 3 sec.-ft. diverted. The 2 sec.-ft. become return flow after serving as a vehicle for carrying the 1 sec.-ft. consumed. Part of the unused water is recovered by drainage canals. Although there are many miles of these canals in use in the North Platte Valley, many more miles must be constructed before return water is efficiently brought back to the stream. It must be kept in mind that some of the unused water returns to the stream through channels other than the drainage ditches. Not all the unused water is returned through drainage canals. Probably the major portion is returned through deep percolation designated as "invisible return flow."

#### RECORDS OF FLOW, RAINFALL, AND TEMPERATURE

Visible return flow, as herein used, includes some waste water. Nearly all projects use drainage canals occasionally to conduct excess water back

to the stream, and it has not been practicable to separate the waste water from the seepage. There is also surface water from irrigated fields bordering along the drainage canals that must be taken as visible return flow. The visible return flow of the North Platte River between the Wyoming-Nebraska Line and Bridgeport amounted to 630 000 acre-ft. for 1926. Fig. 2 shows the yearly quantity of visible return flow each year from 1912. The three rather pronounced jumps—1916, 1919, and 1924—are accounted for probably by preceding wet years.

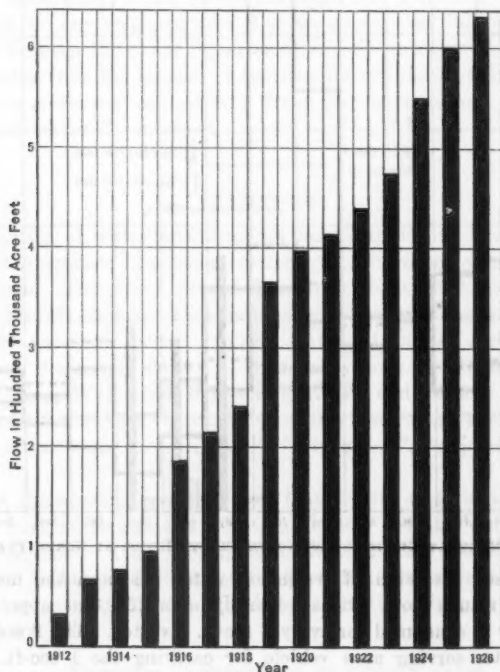

FIG. 2.—VISIBLE RETURN FLOW BETWEEN WYOMING-NEBRASKA STATE LINE AND BRIDGEPORT, NEBR.

The records of precipitation between Whalen and Bridgeport furnish the following information: During the irrigation season (May to September, inclusive) of 1915, the rainfall was 8.5 in. and the year's rainfall was 11.6 in. above normal; the record for the 1918 irrigation season showed 5.3 in. and the annual precipitation was 7.0 in. above normal; and for the season of 1923 the recorded rainfall was 4.6 in. and the annual quantity was 4.4 in. above normal. These are the greatest precipitations recorded since 1912, and the three wet years preceded the years that show the marked gain. The years 1916, 1919, and 1924 show the lowest precipitation since 1912, with the exception of 1914, which was 6.0 in. below normal.

The temperature during the irrigation seasons was below normal in 1916 and 1924, and considerably above normal in 1919. High temperature and hot winds diminish the visible flow. In Western Nebraska water is diverted for irrigation between May 1 and October 1. The diversions are greatest in July and August, and the return flow, in September and October, the lowest being about the last of April. The quantity of visible return flow available for use during the irrigation season of five months is approximately 48% of the annual visible return flow.

#### VARIATIONS IN RETURN FLOW

At Whalen, the United States Bureau of Reclamation operates and maintains a concrete diversion dam. Immediately above the dam two large canals, one on each side of the river, divert from the river during the irrigation seasons a quantity of water varying from 2 000 to 3 500 sec-ft. Special efforts were made to procure accurate data on the return flow between Whalen and Bridgeport during the years 1925, 1926, and 1927. There was a gradual increase in return flow from station to station down the river. For example, in August, 1925, it was found that there was no return flow at Whalen.

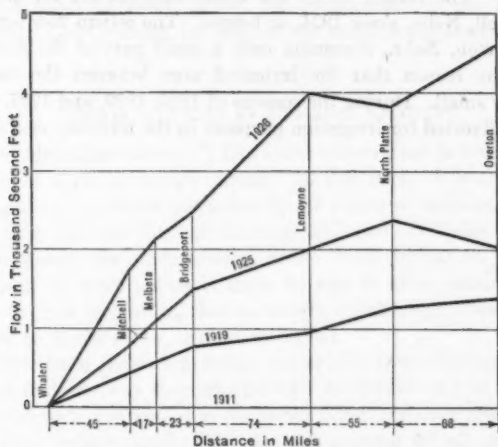

FIG. 3.—TOTAL ACCUMULATIVE RETURN FLOW, FIVE MONTHS.

The flow gradually increased at successive stations down the river until at Bridgeport, a distance of 93 miles, the mean daily return flow was 1 869 sec-ft., of which 57% was visible return flow. The remainder was invisible coming into the river from deep percolation and probably not all should be classed as return water. Rainfall in the basin contributes considerably to the invisible flow and causes it to vary. It is impossible to determine what part is rainfall.

The quantity of water returning in a comparatively short time is remarkable. Fig. 3 shows graphically the marked increase. This diagram includes

both visible and invisible flow. There is a very great increase in 1926, and the records for 1927 confirm the 1926 curve. The precipitations for 1925, 1926, and 1927 were practically normal. The temperature was above normal in 1925 and 1926 and considerably below normal in 1927. The diversions for 1925, 1926, and 1927, between Whalen and Bridgeport, were 1 229 000, 1 935 000, and 1 171 000 acre-ft., respectively. The visible return flow shows in Fig. 2, a uniform increase for these three years. The astonishing increase for 1926, as shown in Fig. 3, is the invisible flow, which comprises return water through deep percolation from the irrigated area and precipitation through deep percolation from the entire area of the drainage basin. Years of large precipitation and low temperatures are favorable to greater invisible flow.

No storage water was available for use in the valley until after the completion of the Pathfinder Reservoir in 1910. Since that year storage water has been used to supplement the direct flow. During the 1927 season, storage water was used on approximately 184 000 acres between July 1 and September 30. The direct flow was used on the remaining irrigated area between May 1 and September 30. The direct flow comprises the natural head-waters of the Platte Rivers, together with the return water from the irrigated area of the basin. The return water has been sufficient for all diversions made east of Mitchell, Nebr., since 1924, or longer. The return flow between Bridgeport and Overton, Nebr., comprises only a small part of the total flow of the stream for the reason that the irrigated area between the two stations is comparatively small. During the seasons of 1925, 1926, and 1927, about 270 000 acre-ft. were diverted for irrigation purposes in the territory east of Bridgeport.

## DRAINAGE RECOVERY FROM IRRIGATION

BY D. W. MURPHY,\* M. Am. Soc. C. E.

### SYNOPSIS

In the practice of irrigation a part of the water applied sinks below the zone of plant growth and is wasted. It is possible, in many instances, to recover a portion of this underground waste through drainage. The quantity that can be recovered depends largely on the character of the underground formation.

The feasibility of recovering irrigation wastes through drainage depends on the cost of draining the water out of the subsoil and its value at the point where it can be collected and discharged. On areas where drainage is necessary to protect soils from becoming water-logged and alkaline, the value, if any, of the water recovered is a net gain.

In the Salt River Valley in Arizona the water pumped to drain and protect the soils is a valuable asset: First, for supplementing the gravity supply during dry years; and, second, for sale for use on adjacent lands.

### WHAT IS MEANT BY DRAINAGE RECOVERY

The term, "drainage recovery", like many others used in irrigation practice, is susceptible of various interpretations. In this paper it is applied to waters used in irrigation, which are not taken up by plants or evaporation and so can be removed from the soils through drainage and made available for further use. It is, so to speak, the underground waste from irrigation which may be recovered from the soils before it finds its way to some natural watercourse. Surface waste from irrigation, that is, waters which merely flow over the lands and off them as surface flow, are not included.

Return flow from irrigation differs materially from drainage recovery. It is water that finds its way through the soils downward and by lateral percolation to natural watercourses. On the other hand drainage recovery may, and ordinarily does, reduce return flow through cutting off all or a part of the water that would otherwise find its way to natural watercourses. It tends also to prevent evaporation from the surface by maintaining the water-table at a lower elevation and thus reducing the quantity of water brought to the surface through capillary action.

### CONSUMPTIVE USE OF WATER

The total quantity of water applied in irrigation may be stated in terms of consumptive use by plants, of surface evaporation, and of waste, both surface and underground. Drainage recovery is dependent, it may be said, primarily

\* Cons. Engr., Los Angeles, Calif.

on the last factor, underground waste. The amount of underground waste varies greatly for different conditions. The adequacy of a water supply, its cost, the method of application, and the character of soils, all may influence it.

From the few determinations that have been made on the consumptive use by plants, it appears that a large part of the water applied in irrigation is lost either through evaporation or waste. In studies made over large areas in Southern California, the conclusion was reached that 1.82 acre-ft. per acre per year represented the average consumptive use by plants. From this, it appears that with ordinary irrigation a large part of the water applied is lost or wasted, so far as the area to which it is applied is concerned. It indicates also the probability of considerable underground waste and the possibility of large quantities being recovered through drainage.

#### WATER THAT MAY BE RECOVERED

The quantity of irrigation water that can be recovered can never exceed that of underground waste, and it may be but a small, even a negligible, part of such waste. The factors that control the amount of recovery, assuming that the underground waste is a material quantity, generally include soils and the character of the underground formation. It is possible to conceive of an area lying in a closed rock basin out of which no waste from irrigation can escape. In such a case it is possible, through drainage, by pumps and wells, to recover all, or practically all, the irrigation waste from the given area.

The same is also true, but in a somewhat lesser degree, in many valleys with relatively narrow outlets. Practically all the waste into such valleys can be pumped out by a proper and judicious placing of drainage wells. Such areas exist at many places in the Valley of the Rio Grande, and also in those of other Western rivers. The conditions necessary for this kind of action are: First, a closed or nearly closed valley for holding the irrigation water; and, second, a valley fill sufficiently pervious to permit relatively free passage of water through it and to serve as a medium in which the waste waters may be collected. These represent extreme conditions favorable for drainage recovery.

It is equally possible also to conceive of an area not bounded by any rock or other impervious materials, from which underground waters can escape with relative freedom. Where this is the case the irrigation waste flows away more freely, and little or none of it can be collected by drainage works. Such areas are sometimes found on sandy or gravelly mesas adjacent to streams, and in valleys which widen rather than contract toward their lower ends.

Another condition which makes difficult the collection of drainage water is a shallow, comparatively pervious top stratum overlaid by impervious materials. The drainage of such a formation ordinarily must be accomplished by cutting into the impervious materials and collecting the waste water in such excavations by the slow process of flow or percolation over the top of the impervious stratum. Such a condition permits of little storage capacity in the soils. Furthermore, it is difficult to collect the drainage water in large quantities, except through a long system of drains. In such cases the drainage discharge may be at the extreme lower portion of the irrigable area.

## FEASIBILITY OF RECOVERY BY DRAINAGE

There are several practical and economic questions to be considered in connection with drainage recovery of irrigation water. Among these may be mentioned the following:

- (1) The quantity of water that can be recovered.
- (2) The quality of water, that is, its fitness for use in irrigation.
- (3) The cost of recovery.
- (4) The location at which water can be delivered.

The quantity of water that can be recovered may vary from nothing to possibly as high as 20 or 25% of that applied in irrigation. It may even exceed this percentage on limited areas. Large underground wastes in irrigation are most commonly experienced during the early stages of a development. This is due in large part to the limited experience of settlers in irrigation and also to the more abundant water supply available in the first stages for development. Experience together with the greater demand and consequent increased value of water, tends gradually to reduce waste in irrigation. For this reason a water supply which depends wholly, or in large part, on drainage recovery may be reduced in future years, due to more economic and better use of water in irrigation.

It is clear that irrigation waste is due, in large measure, to man's inability to deliver water to land in the most efficient manner. Further, it is impossible to predict with any degree of certainty how much water can be recovered from a given area in advance of actual irrigation and drainage of that area. Information concerning the quantity recovered from one area is of little value for another, due to the many variable factors in each.

## QUALITY OF DRAINAGE WATER

The character of drainage water must be given consideration in every case where it is to be used for irrigation purposes. This feature is difficult, due to the fact that there is no fixed standard by which the quality can be readily compared. There was a time when soil chemists were willing to state with some degree of positiveness that water containing more than a certain amount of harmful alkali salts was unfit for use in irrigation. Many contradictory experiences have somewhat modified these ideas, so that now most soil chemists and engineers are willing to admit that water containing slightly more than this specified amount may not be unfit for use and that if it contains less than the specified amount, it may not be good.

## COST OF DRAINAGE AND VALUE OF WATER RECOVERED

The cost of draining irrigable areas ordinarily is an obligation that must be met for the protection of lands, whether or not the water drained off can be utilized. Up to a certain point the cost of drainage works cannot be charged against the supply attained through drainage. It frequently, happens however, that the expense of conveying a drainage supply to a locality where it can be utilized is high, and consideration must be given to it. This leads at once to the fourth consideration as to where the recovered drainage water can be delivered.

In many areas of extreme aridity where the water supply is the controlling factor in determining the extent of agricultural and other development, attention should, and is being, given to drainage recovery to supplement other supplies that are well nigh exhausted. In such cases the value of water is generally sufficient to justify any reasonable expense that must be incurred in order to obtain a supply.

In areas where there is more water than is required to irrigate the available supply of land, economic questions are of first importance in drainage recovery. In any event each individual case must be given independent study and consideration. There is not sufficient experience to permit of such generalities as that all drainage water should be utilized. Neither can it be said that it is not feasible to recover drainage water, since it has been shown through actual experience that in some localities it is economically and otherwise feasible.

It is evident, in the truly arid regions, that agricultural and other developments will require all the available water supply within a few years. It is necessary in such areas to give consideration to conserving the entire supply. This will require a curtailment of irrigation water or a recovery of such wastes through some form of drainage. It is reasonable in this connection to assume that no single method can or will be used in such conservation, but that waste from irrigation will be reduced to a minimum through better methods of use, and that unavoidable waste will be recovered as far as practicable.

#### EXAMPLE OF DRAINAGE RECOVERY

The most noted instance of recovery of water through drainage that has come within the writer's experience is in the Salt River Valley in Arizona. The irrigable area within the project is about 200 000 acres. After irrigation had been in progress for a number of years the water-table rose, over a large part of the area, sufficient to threaten the irrigability of the soils; and over a considerable area, sufficient to render them unfit for cultivation, due to water-logging and the accumulation of harmful alkali salts on or near the surface.

The plan considered most feasible for draining the valley was by means of wells sunk to depths varying generally from 150 to 300 ft. The formation of the valley is such that pumping from deep wells has a direct effect on the elevation of the water-table; that is, the water-bearing materials of the upper and lower portions of the valley fill are sufficiently connected to cause a general lowering of the ground-water by pumping from deep wells.

In deciding on the plan of using wells for drainage, it was the intention that the water pumped from the soils would be used, in so far as possible, to augment the natural irrigation supply for the project which comes from Roosevelt Reservoir. With this end in view, wells were located, consistent with drainage requirements, so that water could be pumped directly into canals or laterals and used on the lands of the project.

On a part of the area where the pumped waters have not been regarded as needed for supplementing the gravity supply, they have been sold to be used

on outside lands. The following tabulation gives the quantities pumped by years, from 1919 to 1926:

Year.	Acres-foot.
1919-20 .....	55 833
1920-21 .....	55 368
1921-22 .....	109 211
1922-23 .....	152 464
1923-24 .....	167 000
1924-25 .....	309 703
1925-26 .....	251 432

All or practically all this pumped water was used for irrigation to supplement the gravity supply.

The system of drainage by wells has an advantage over any system of drains for water recovery. A heavy draft can be made on the ground-water supply during the irrigation season, or during years of short gravity supply, and pumping can be discontinued during the non-irrigation season, or when pumped water is not needed. By this method of operation the water-table can be maintained at all times at a safe distance below the surface and, at the same time, the underground storage supply can be largely conserved.

## DISCUSSION

R. I. MEEKER,\* M. Am. Soc. C. E. (by letter).—The question of return-flow water from irrigation is recognized by engineers as a large factor in river supplies and it is beginning to be appreciated generally by water users on river systems in all the Western States.

Uncertainties concerning dependence on seepage water from irrigation as a large factor in water supplies, long ago passed from the field of speculation in Colorado, where pronounced return-flow waters from irrigation have developed; where seepage or return-flow measurements were initiated in 1885;† and where such measurements have been systematically made to date (1928).‡ The increasing volume and magnitude of such waters are a revelation to the water users in the more recently irrigated areas of the North Platte Valley. If head-gate diversions were a total loss to the North Platte River—as used in water supply studies in 1914—the then threatened interstate water shortage of three States would have become a certainty by this time. Present measurements of return-flow or seepage waters in the North Platte Valley, together with recent engineering data on net water requirements of irrigated lands in older irrigated valleys, are sufficient bases for the assertion that the water supply of the North Platte Basin is sufficient, when controlled by reservoirs, for the needs of three States, with water to spare.

Return-flow measurements and consumptive-use determinations of irrigated lands supplement each other, go hand in hand, and are destined to play a large part in the future irrigation history of rivers. A non-allowance for return-flow water in engineering studies of river supplies will result in a restricted forecast of acreage of lands which may ultimately be served. The beneficial and healing effects of return flow have turned many an irrigation ditch, initiated prior to the set-up of such flow, from failure to success. Return flows from irrigation usually set up slowly and progressively, and may require from ten to twenty years to reach a stabilized condition, dependent on soil conditions, topography, and water usage.

No better illustration of the benefits to be secured from soil storage of water is to be had than that in Fig. 1 on which the natural run-off of the North Platte River is shown, with September and October low flows increased 200 per cent. In recent years the winter flow of this river at Bridgeport, Nebr., has been chiefly return flow.

In the river section between Whalen, Wyo., and Bridgeport, drainage recovery on the North Platte Project has been a large factor in the heavy volume of return flow shown in Fig. 2. At the close of 1927 the drainage system of this project consisted of 350 miles of open-drain ditches costing \$1 400 000. This project is a large factor in the heavy seepage and return-flow waters of the North Platte River section from Whalen to Bridgeport. Of the 350 000 acres now irrigated in this section, 170 000 acres are lands of

\* Cons. Engr., Denver, Colo.

‡ Biennial Repts., State Engr. of Colorado.

the Federal Project. According to records of the U. S. Bureau of Reclamation, head-gate diversions of the project now average almost 650 000 acre-ft. per year.

With present information a correlation of head-gate diversions, return-flow data, and consumptive-use determinations of the North Platte Valley between Whalen Dam and Bridgeport, where 350 000 acres are irrigated, shows the following relations concerning water used for irrigation:

Head-gate diversion, 3.50 acre-ft. per acre per year.....	100%
Return flow, 2.30 acre-ft. per acre per year.....	67%
Consumptive use of river water, 1.20 acre-ft. per acre per year..	33%

With respect to return flow, the irrigated lands of the North Platte Valley in Wyoming and Nebraska are commencing to function in a manner similar to the irrigated lands of the South Platte Valley in Colorado. On account of the more abundant water supply, with consequent lavish use on the irrigated lands, larger return flows per unit of area irrigated are to be expected in the North Platte Valley.

*South Platte Valley Return Flow.*—The irrigation history of the South Platte Valley in Colorado, furnishes the confirmatory background of what may be expected as to return-flow waters in the North Platte Valley when irrigation conditions become stabilized. Return-flow measurements have been made systematically in the Colorado irrigated areas beginning about 1888. A recent determination of return-flow waters to the channel of the South Platte River (in a distance of 236 miles, extending from a point at the foothills 20 miles above Denver to Julesburg, Colo.) shows a gain of 6 sec-ft. per mile of channel, a total gain of 1 475 sec-ft., which is equivalent to a yearly return of 960 000 acre-ft. These figures apply only to the channel of the river and do not include the return-flow waters of tributary streams, such as Bear and Clear Creeks, St. Vrain, Big Thompson, and Cache la Poudre Rivers, on which large acreages are irrigated. All these streams are recipients of return flow in considerable quantities, and, although such waters are re-diverted and re-used within their own basins, considerable volumes of return flow annually reach the channel of the South Platte River. Such tributary inflow is excluded from river gains.

As an illustrative example of the beneficial and healing effects of return-flow waters, the changed status of the Lower South Platte Valley, from Kersey to Julesburg, is cited: 240 000 acres are now irrigated in this section, as compared with only 100 000 acres in 1902. This region depends almost exclusively on return flow for its water supply. Five reservoirs with a total capacity of 275 000 acre-ft. store and control the winter return flow. In 1902, the Lower South Platte Valley was considered the poorest section of the South Platte River for water supply. To-day, water conditions are just the reverse. In 1925, a low-water year (60% on mountain run-off), the junior ditches and reservoirs of the Lower South Platte Valley received an adequate water supply and the best supply of any section of the South Platte Basin, whereas upper areas, under senior ditches dependent on direct-flow water from the mountains, suffered water shortages.

Table 1 shows in a comparative way the progressive increase of return flow to the main channel of the South Platte River from the head of the irrigated area to the Colorado-Nebraska line, as determined by return-flow measurements covering a period of thirty-five years. The table was prepared from records filed in the office of the State Engineer of Colorado.

TABLE 1.—RETURN-FLOW WATER TO MAIN CHANNEL, SOUTH PLATTE RIVER, PLAINS AREA, EASTERN COLORADO, FROM PLATTE CANYON TO JULESBURG, COLORADO, 236 MILES OF RIVER CHANNEL.

Year.	Total second-feet.	Acre-feet per year.
1891.....	580	375 000
1900.....	880	570 000
1908.....	1 200	775 000
1916.....	1 410	915 000
1926.....	1 480	1 000 000

Evidence of the large return flows of the South Platte Basin and consequent re-use of water may also be best indicated by the statement that with an average inflow of mountain water of 1 500 000 acre-ft. per year, 1 100 000 acres are irrigated, and still the unused residue passing to Nebraska is 400 000 acre-ft. per year. A large return flow from soil storage with re-diversion and re-use several times is the answer.

*Literature on Return Flow.*—The following literature on return flow is cited for convenience of engineers who have need of information on this important subject:

FRED H. TIBBETTS,\* M. Am. Soc. C. E. (by letter).—When an irrigated valley is generally underlaid by a water-bearing formation of substantial vertical dimensions and readily available porosity ("specific yield"), and particularly when such a valley is irrigated in large part from reservoir releases such that the accumulation of impounded water is subject to the great annual variation of arid sections, economic studies will then probably show that full development will indicate extensive occasional use of the underground formation for cyclic storage. This general hypothesis is steadily becoming evident in regions like the Salt River Valley of Arizona and the San Joaquin Valley of California. Deep percolation will gradually fill the water-bearing formation with water which, especially if the outflow at the lower end is blocked or retarded, will be protected over a period of years from the large evaporation losses of surface reservoirs, and will then be available during seasons of great water shortage when, by pumping from wells, it can be recovered and used. In such cases it will quite probably be found to be more expensive to distribute the water (including the pumping lift) from the underground reservoir than from surface reservoirs. However, inasmuch as the increase in cost is for power for pumping, this item, felt only during the infrequent cycles of particularly dry years, will not affect greatly the average cost of water.

It is likely that an ultimate balance on large sized projects of from 400 000 to 600 000 acres, will be found when from 10 to 30% of the total water supply is obtained by pumping. The Salt River Valley, the San Joaquin River Water Storage District, and the Pine Flat Storage District (Kings River, California) would be included in this class. In cases of emergency when surface reservoir supplies fail there will be available the possibility (by pumping down the water plane) of furnishing a large part of the required water in this way. Pumping operations of this kind may be perfectly feasible, especially in occasional emergencies, if the aggregate depth of available water-bearing formation within the limits of about 300-ft. wells, is as much as 40 ft. of gravel or sand in which the specific yield under field conditions is about 15 per cent. In such a case a total of 3 ft. of water per year is theoretically procurable, for two successive years from this source alone.

As a further contribution to the subject of return water the writer wishes to present briefly a highly specialized case which apparently violates all the rules of orthodox irrigation engineering in that it seems to demonstrate that the more water used the better for everybody.

The rice industry in California, starting in 1912 with 1 400 acres, increased in 8 years to 162 000 acres. In 1919, the rice crop was valued at more than

\* Civ. Engr., San Francisco, Calif.

\$21 000 000. Although rice growing is the greatest of cereal industries, it has nowhere else been introduced quickly on arid lands requiring large quantities of irrigation water with a relative shortage of cheap labor. In California, where labor is scarce and costly, Oriental methods must be modified so as to require a minimum labor cost in preparing and tilling the land, and particularly in irrigating and harvesting the crops. One method of accomplishing this result is to allow the diversion of excessive quantities of irrigation water. Experience has shown that on the areas best adapted to rice culture, the encouragement of such excessive diversions does not lead to the wastage of water and hence the impairment of irrigation water resources.

Analysis of return water from rice irrigation has the simplicity of a textbook problem, because all the water diverted can be completely and accurately accounted for. On three typical projects in the Sacramento Valley—one irrigating about 40 000 acres of rice, another about 10 000, and another about 900—the irrigation diversions have been measured since 1919. The waste or excess water from these projects is almost immediately collected in drainage canals and returned to the Sacramento River, and again is accurately measured within a few miles of its diversion point. In the typical rice operations of Reclamation District 108, in Colusa Basin, where about 10 000 acres are under irrigation, water is diverted from the river by pumping or by gravity, depending on the river stage. It is then returned to the river within 18 miles of the diversion point in the same manner. Fig. 4 shows for each year since 1919, the average diversion per acre irrigated, segregated into the “consumptively used” water and the water immediately returned to the river. The point that the writer wishes to emphasize is that the consumptive use of the water, and hence the quantity extracted from the river, is practically independent of the quantity diverted. The net extraction is equivalent to a depth of about  $5\frac{1}{2}$  ft., and whatever the diversion from the river the remainder, in excess of  $5\frac{1}{2}$  ft., is immediately returned.

The drainage water is concentrated in deep drainage canals so that the surface of the water in the canals is generally below the ground-water level during the irrigation season, and always so when adjacent to the rice fields where the land is kept continually submerged. Rice irrigation should be, and in the main is, restricted to heavy soils such as clays and clay-adobes, in which loss of water by deep seepage and percolation is negligible. In soils of these types the seepage is excessively slow. Furthermore, the distance through which the drainage water is transported is so small that evaporation losses are negligible. The result is a clear-cut condition in which the drainage water, or return seepage water, is essentially the diverted water, less the water used in irrigation. The latter represents evaporation losses in the beginning of the season, and when the rice plants are high enough to shade the soil, it represents principally transpiration losses through the growing plants. The average consumption of water from these causes is shown in Fig. 5 for the irrigation season of April, May, June, July, August, and September, in inches per month. This is much in excess of the normal evaporation losses from a free water surface.

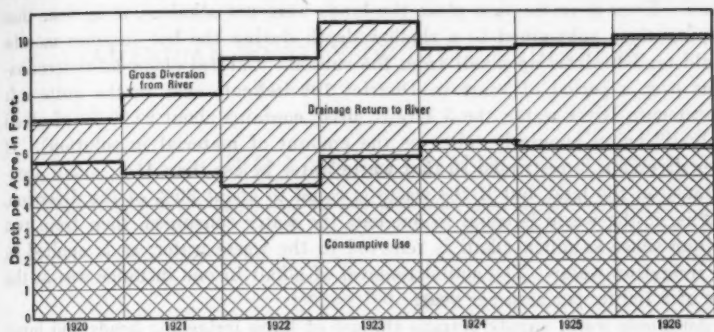

FIG. 4.—ANNUAL DIVERSION, USE, AND RETURN, RECLAMATION DISTRICT NO. 108.

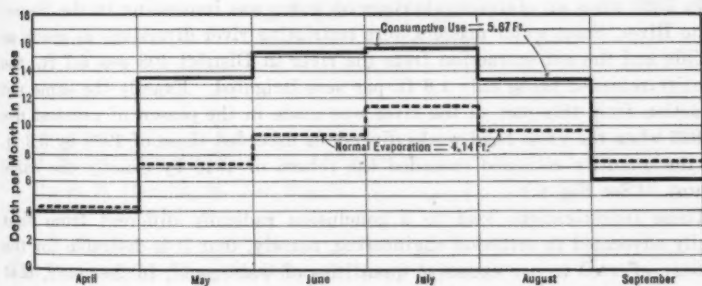

FIG. 5.—AVERAGE CONSUMPTIVE USE AND NORMAL EVAPORATION.

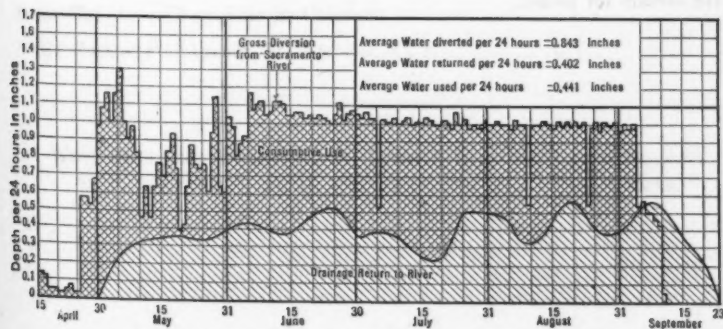

FIG. 6.—TYPICAL SEASONAL DIVERSION, USE, AND RETURN.

One of the advantages of rice irrigation in California is that it makes possible the utilization of lands formerly considered of little value because of alkali. Even if in the first place the lands were not alkaline, it is clear that keeping them submerged to a shallow depth during the hot summer months would tend to draw up alkali from the subsoil. Careful chemical determinations over a period of years in District 108 indicate that in the quite soft Sacramento River water, the 5 acre-ft. used, contains about 2 000 lb. of alkali ("alkali" being popularly taken as the amount of material in solution). If river diversion is restricted so that waste water is less than 15%, alkali accumulates on the land, but if the waste is equal to about 30% of the diversion, that is, if the waste is equal to one-half the water consumed, then from two to four times as much alkali is removed in the waste water, as is applied in the irrigation water. The actual removal of alkali in one instance was at the rate of 9 750 lb. per acre per year.

An ample water supply permits the use of large irrigating heads and large rice checks, with a substantial reduction in labor cost for preparing the soil and distributing the water. Free flow through large checks keeps the water fresh, and tends to maximum yields and early maturities.

In 1920 when an alarming shortage of water was impending in the Sacramento River, State water masters were restricting river diversions as much as possible and the net extraction from the river in District 108 was 5.7 ft., the quantity returned being only 1.6 ft. per acre irrigated. Exactly the same net extraction from this part of the river was made in the season of greatest use in 1923 when the gross head-works diversions exceeded those of 1920 by 3.3 ft. and the quantity returned exceeded the return of 1920 by exactly the same amount. (See Fig. 6.)

These investigations lead to a conclusion radically different from that usually advocated in orthodox engineering, namely, that it is desirable for the industry affected to use excessive quantities of water, and, furthermore, that such excessive use is not a public injury because the available water supply is not diminished thereby. Quantities of water diverted, in excess of the normal consumptive use of about 5½ ft., are immediately and with certainty returned to the stream for re-use.

## INTER-WATER-SHED DIVERSIONS BY TUNNELS ON UNITED STATES RECLAMATION PROJECTS

By E. B. DEBLER\*, M. AM. SOC. C. E.

### SYNOPSIS

Trans-mountain diversions, from the Colorado River drainage area to adjacent basins, for irrigation and other uses, have received much consideration in connection with the proposed construction of the Boulder Canyon Reservoir and the proposed compact for the allocation of the Colorado River waters. The aggregate total of such diversions is expected to exceed, in the ultimate, 500 000 acre-ft. per year. One of the most important of these is the Strawberry Tunnel Project, constructed by the U. S. Bureau of Reclamation to irrigate lands in the vicinity of Provo, Utah. Another trans-mountain diversion, although not diverting away from the Colorado River Basin, is the Uncompahgre Tunnel, between Uncompahgre and Gunnison Rivers in Colorado, serving the Uncompahgre Project. This 6-mile tunnel, at the time of its construction (beginning in 1904) was the longest tunnel in the United States, and the most imposing undertaking up to that time in connection with irrigation.

### THE GUNNISON TUNNEL

*History.*—The Uncompahgre River is a tributary of the Gunnison River which, in turn, enters the Colorado River at Grand Junction, Colo. The lower portion of the Uncompahgre traverses a broad fertile valley without sufficient rainfall for crop production and with local stream flows inadequate for the irrigation of the valley. Paralleling this valley and separated from it by a mountainous ridge lies the Gunnison River (Fig. 1) with a flow very much greater than that of the Uncompahgre and devoid of bordering irrigable areas capable of using material portions of its flow. Furthermore, the Gunnison River lies at uniformly higher levels than the Uncompahgre Valley.

Rapid settlement of the valley started in 1884, and numerous large irrigation canals were constructed before stream discharge data had become available. It was soon found that with 100 000 acres under irrigation less than 30 000 acres could reasonably be expected to receive an adequate water supply from local sources.

The diversion of Gunnison River water to the valley was conceived in 1890 by Mr. L. C. Lauzon. In 1894, surveys were undertaken by popular subscription. In 1901, the Colorado State Legislature appropriated \$25 000 for the location and construction of a Gunnison Tunnel but, in 1902, these funds were exhausted after a tunnel had been driven 900 ft. In 1901,

\* Engr., U. S. Bureau of Reclamation, Denver, Colo.

investigation of the Gunnison Tunnel plan was undertaken by the U. S. Geological Survey under the direction of Mr. A. Lincoln Fellows, the work in 1902 being transferred to the newly created Reclamation Service. A new tunnel location was adopted in 1904, following extensive surveys.

FIG. 1.—MAP OF GUNNISON TUNNEL AND UNCOMPAHGRE PROJECT, COLORADO.

Plans and specifications for the tunnel were completed in July, 1904, and in the October following, a contract was awarded the Taylor-Moore Construction Company, of Hillsboro, Tex. The contractor withdrew from the work in the following May, after completing about 4.3% of it. In August, 1905, an advertisement was issued for bids on the completion of the work, but those received were considered excessive. The work was then undertaken by the Reclamation Service with plant and equipment turned over by the defaulting contractor, with subsequent additions thereto. The tunnel was holed through on July 6, 1909, and enlarged to full section in February, 1910.

*Tunnel Section and Materials.*—The tunnel has a length between portals of 5.8 miles. In general, the interior section presents vertical side-walls, 11 ft. apart, surmounted by an arch of 6 to 8 ft. radius, with the crown 12 ft. above the floor. The principal variations during construction related to changes in the radius of the arch to care for changing conditions.

The materials encountered, starting from the west portal, were as follows:

- For 2 000 ft., alluvial deposits of sand, gravel, and clay, all water-bearing and very heavy.
- For the next 1 200 ft., the same materials with a gradually rising bed of hard shale requiring careful timbering to support the roof and blasting to remove the bench.
- The following 10 000 ft., black shale containing inflammable and explosive gases, but dry.

Then 2 000 ft. of badly faulted and shattered mixtures of sedimentary rocks and coal containing gases, and much hot and cold water. Finally 15 380 ft. of metamorphic granite, gneiss, and schist of greatly varying hardness, with frequent seams carrying much water.

*Construction Plan.*—The general plan of construction in the alluvial formations was by means of a 4 by 6-ft. top entry, followed by the opening of the arch haunches and sides, with subsequent removal of the bench. In hard formations a top heading, 6 to 8 ft. in height and of full width, was followed by benching.

Timbering was required on about 18 000 ft., or 60% of the tunnel length, almost evenly distributed between ground materials requiring immediate timbering and harder shales permitting a lag of several days behind the bench excavation.

The concrete lining was largely completed by June, 1910, with some lining placed in 1912, and small amounts subsequently. The original plans contemplated full lining, but actually only the floor is wholly lined, with the sides and top lined throughout somewhat more than one-half the length. The tunnel costs, including portals and portal cuts, were roughly \$2 900 000, including construction roads and engineering, or about \$500 000 per mile.

*Utilization.*—With full concrete lining as originally contemplated, the estimated capacity of the tunnel was to be 1 300 sec.-ft. With the partial lining thus far installed, the maximum diversion has been 975 sec.-ft. The original estimated area of irrigable lands in the project was, roughly 140 000 acres. Modifications of the planned distribution system, following the acquisition of numerous existing canals and their adaptation to the project in preference to the construction of new canals, together with seepage developments and the inferior quality of some of the lands originally included, leaves an area of 95 000 acres of good irrigable lands, of which 65 000 acres are now irrigated (1927).

The principal impediment to extension of the irrigated area is widespread seepage without sufficient general interest by the land owners for the adoption of a comprehensive drainage program. For the irrigated area, the delivery of water to the land has averaged 5.7 acre-ft. per acre annually. With a moderate improvement in the duty of water, the combined water supply available from the Uncompahgre River and through the Gunnison Tunnel in its present condition, is estimated to be sufficient for the irrigation of about 85 000 acres.

An increase in the tunnel capacity would not be reflected in a corresponding increase in water supply, as the present capacity is in many years greater than the flow of Gunnison River for varying periods in late summer. The Gunnison has no storage control, but an excellent reservoir site on Taylor Fork has been withdrawn from entry and set aside for use by the Uncompahgre Project in case it should become desirable to increase the low-water flow of the stream in connection with an increase in the tunnel capacity by the completion of the lining.

The annual diversions through the Gunnison Tunnel, all used for irrigation, have averaged 237 000 acre-ft. for the 5-year period ending with

1926. The construction charge payable to the United States for the Gunnison Tunnel and for the construction and reconstruction of canals and laterals is \$52 per acre. The principal crops are alfalfa, sugar-beets, and potatoes, with an average annual crop production at the farm of \$44 per acre over the past ten years.

The Gunnison Tunnel is not properly a trans-mountain diversion as the term is usually understood, in that the irrigated area lies along a tributary of the parent stream from which the primary water supply is derived. It is, however, to date (1927), the longest tunnel built for irrigation purposes.

### STRAWBERRY TUNNEL

*History.*—The Strawberry Valley Project (Fig. 2) comprises Strawberry Reservoir with a capacity of 255 000 acre-ft. located on Strawberry River, thirty miles easterly from Provo, Utah; the Strawberry Tunnel diverting reservoir waters westerly through the Colorado River-Great Basin Divide into the Spanish Fork water-shed; and a distribution system for lands in the vicinity of Springville, Spanish Fork, and Payson, Utah.

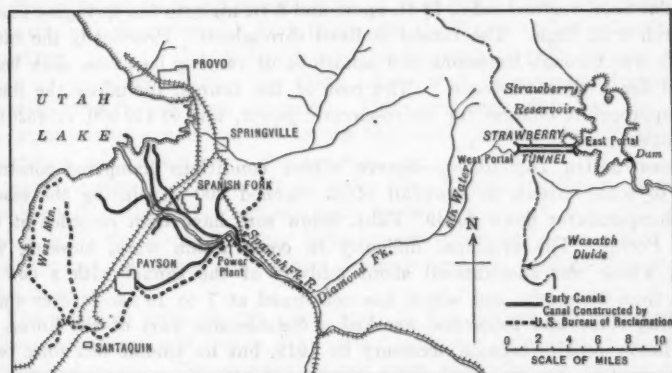

FIG. 2.—STRAWBERRY TUNNEL, STRAWBERRY PROJECT, UTAH.

The diversion of Strawberry River waters to the Spanish Fork Basin received active consideration by the State Engineer of Utah and by irrigators in the Basin about 1900. In 1902, a full survey of the plan was made by a company interested in irrigation storage and power development, but was rejected as too costly.

In 1903, an investigation of the plan was undertaken by the U. S. Reclamation Service at the request of interested citizens, but a number of factors slowed up progress. Among these were the location of the Strawberry watershed within the Uintah Indian Reservation; the extremely low run-off for a few years immediately preceding, indicating a comparatively high construction cost for the estimated yield of water; and lack of adequate interest by land owners to be benefited.

With the definite abandonment of plans to use Strawberry River waters within the Duchesne water-shed, the opening of the Uintah Indian Reservation, and increasing interest in irrigation, a petition for further consideration of the project was received in January, 1905, from about 1 200 citizens. Following the completion of arrangements for repayment of construction expenditures, commencement of work was authorized in March 6, 1906, and \$1 250 000 was set aside for this purpose from the Reclamation Fund. Work was immediately started on roads and telephone lines to the tunnel portals.

In August, 1906, bids were invited for the construction of the tunnel, but as no proposals were received, construction by force account was authorized in September, 1906, and promptly commenced at the West Portal. From July, 1907, to November, 1908, work was suspended awaiting the building of a hydro-electric power plant on the lower reaches of Spanish Fork River to furnish power for tunnel construction. Thereafter work was resumed at the West Portal. In October, 1911, work was commenced at the East Portal. The tunnel was holed through on June 20, 1912, and the concrete lining was completed in November, 1912.

*Tunnel Data.*—The tunnel has a length of 3.6 miles, with an interior section of a flat floor, vertical sides, 7½ ft. apart and 6 ft. high, to the springing line of an arch 2 ft. high. The tunnel is lined throughout. Practically the entire length was through limestone and sandstone of varying hardness, shale being found for a short distance. The cost of the tunnel, including the lining and appropriate charges for hydro-electric power, was \$1 150 000, or \$320 000 per mile.

*Construction Difficulties.*—Severe winter conditions hampered construction to some extent, as snowfall often reached 200 in. during the season and temperatures down to 49° Fahr. below zero have been recorded at the East Portal. The principal difficulty in construction work, however, was water which was encountered about midway of the tunnel with a flow of more than 10 sec-ft. and which has continued at 7 to 10 sec-ft. ever since. Swelling shale and limestone wrecked a considerable part of the lining, so that heavy repairs became necessary by 1919, but no trouble has since been experienced.

*Utilization.*—Strawberry Reservoir, with a capacity of 255 000 acre-ft. available for diversion through the tunnel, is formed by an earth-fill dam with a maximum height of 72 ft. and a length of 488 ft., across Strawberry River, and an auxiliary dam, 37 ft. high and 1 300 ft. long, across a low pass into the Indian Creek water-shed. Early investigations indicated that the cost of collecting water from streams on the north into the reservoir would be excessive in relation to the obtainable water. Indian Creek has been intercepted by a short canal, and an extension thereof to intercept Trail Hollow and other small streams can be made at moderate cost when sufficient demand develops for the water.

The safe annual yield of water from the Strawberry Reservoir is estimated at 80 000 acre-ft., with a possible increase to about 95 000 acre-ft. after complete development. The average draft on the reservoir from 1921 to 1926, inclusive, has been 84 400 acre-ft., which, with 6 000 acre-ft. per year from

tunnel leakage, has been added to the flow of Spanish Fork River, averaging 114 000 acre-ft. annually, for diversion by canals serving about 60 000 acres of land at the southeast border of Utah Lake.

The first canals from Spanish Fork River were constructed in 1851 by Mormon settlers. Long before 1900 serious shortages of water were common, with occasionally disastrous results from over-development of the natural flow of the stream. Large storage reservoir sites were not available on the water-shed, and storage of surplus waters on the stream would have infringed on irrigation rights in Utah Lake. The delivery of foreign waters thus solved a problem that might otherwise have resulted in endless litigation.

Water from the Strawberry Reservoir has been sold to the old canals at an average rate of about \$45 per acre-ft. of annual use delivered in the stream. It was purchased for an average use of 1 acre-ft. of water for each acre to be irrigated, such water being supplemental to the natural flow. It has been customary in connection with the old canals to use such storage water on about one-half the farm area, the remainder of the area receiving a partial supply only and being devoted to appropriate crops.

The Federal Government constructed two new canals, the High Line Canal for the irrigation of about 20 000 acres of new lands lying above the older lands southerly from Spanish Fork River, and the Mapleton Lateral, primarily to deliver waters to Hobbie Creek as a supplemental supply for the canals diverting therefrom. Under the High Line Canal, the average diversion is about  $2\frac{1}{2}$  acre-ft. per acre annually. This very high duty for the intermountain territory is influenced by the high cost of the water, construction charges on this project being \$60 per acre.

Approximately, 10 000 acre-ft. of water from Strawberry Reservoir remain unsold at this time. The present price is \$60 per acre-ft. delivered in the stream, with the demand rather light, as the principal areas which could profitably use the water also require drainage and the combined costs deter development.

The principal crops on the older lands of this project are canning vegetables, sugar-beets, and fruits. The newer lands are more largely devoted to alfalfa and grain. The average annual crop value for the project is \$45 per acre.

The Strawberry Tunnel diversion is the largest quantity drawn from the Colorado River water-shed; in fact, it constitutes roughly 70% of all such diversions now (1927) being made.

## THE PROPOSED LOS ANGELES-COLORADO RIVER AQUEDUCT

By H. A. VAN NORMAN,\* M. AM. SOC. C. E.

### SYNOPSIS

This paper discusses the need, in Southern California cities, for water from the Colorado River, which is the only large unappropriated supply near this district.

A description is given of several of the proposed routes that would ultimately divert 1 500 cu. ft. per sec. Two of these routes are unique in being gigantic pumping schemes, either of which would utilize a large block of power from the proposed Boulder Dam. Two others—gravity routes—are unusual in that they entail the driving of tunnels of heretofore undreamed of lengths.

Surveys have been extended into 18 000 sq. miles of territory in the Colorado desert previously unmapped.

Various types of aqueduct construction are discussed, as well as the economic problems related thereto.

### A NEEDED IMPROVEMENT

The recently proposed Los Angeles-Colorado River Aqueduct to provide a municipal water supply from the Colorado River for the City of Los Angeles, and such other cities of Southern California as care to join with her in this enterprise, is unique in two respects. It is to be of greater carrying capacity than any previously constructed aqueduct, and it is not to be in its entirety of the usual gravity type.

The City of Los Angeles now has a population of 1 230 000, and has been growing at a rate which has averaged more than 70 000 inhabitants per year since about 1917. A careful investigation of its present water resources shows that it will reach the limit of its supply by 1937.

Also, in the vicinity of Los Angeles are many suburban cities, some of which are increasing in population even faster, relatively, than that city itself. Some of these cities even now (1927) feel the pinch of water shortage, and many of them see the limit of their supply within a comparatively short time.

In order that these smaller cities may participate in the Los Angeles-Colorado River Project, an Act providing for the formation of Metropolitan Water Districts for the purpose of developing, storing, and distributing water for domestic purposes, was recently passed by the Legislature of the State. Under this Act such a district may be formed of the territory included within the corporate boundaries of any two or more municipalities.

\* Asst. Chf. Engr., Dept. of Water, City of Los Angeles, Los Angeles, Calif.

### THE COLORADO RIVER SUPPLY

Unlike most other cities of its size, Los Angeles is at a great distance from any large source of water supply. Realizing this fact, and knowing the time it would take to construct an aqueduct from any distant source, William Mulholland, M. Am. Soc. C. E., Chief Engineer and General Manager of the Water Department, whose duties require him to look into problems of this nature, began, in 1922, to study the sources from which an additional supply might be obtained.

The Colorado River is practically the largest dependable supply situated at a distance that is not prohibitive in point of cost, and available with the fewest legal and engineering difficulties. Its distance from Los Angeles is similar to that of the Owens River, from which the city completed its first aqueduct about 1912.

The unappropriated surplus flow of the Colorado River is more than sufficient to meet the domestic needs of all the cities of Southern California. Unfortunately, this river in its lower reaches is situated at about the same general elevation as most of the territory to be served, and intervening between it and the Pacific Coast, lies a high mountain range, and a great area of relatively high desert. It is impractical to tunnel either in its entirety, and consequently, if the cost is to be kept within reasonable limits, the proposed aqueduct must be constructed at a level higher than its source. The problems to be solved are, therefore, mainly those of engineering.

With these general facts in mind, a party of engineers, headed by Mr. Mulholland, left Los Angeles on October 29, 1923, for a reconnaissance of the territory as far as the Colorado River, in order to investigate the feasibility of the project. Information obtained on this trip showed not only that an aqueduct could be constructed from the river to Los Angeles, but also that several routes were available.

Much of the country traversed consisted of vast desert waste land, separated by rugged mountain ranges acting as barriers. The greater part of the desert section was unmapped, and it soon became apparent that surveys would have to be made on an extensive scale. On the return of the party, machinery was set in motion for perfecting an organization, and making the necessary preliminary surveys.

### SURVEYS

The geodetic control was based on the Texas-California arc of primary triangulation, of the U. S. Coast and Geodetic Survey. Such points of the Geological Survey as were available in the region, were used, and a system of triangulation control was adopted to extend the work into the new territory. North American datum for position and mean sea level for elevation were adopted as standards for this survey.

The grid system used by the U. S. Coast and Geodetic Survey for the polyconic projection of maps, was taken as a basis for platting. The One Hundred and Sixteenth Meridian, lying about midway between the Colorado River and the Pacific Coast, was taken as the meridian of reference for map work.

All the topographic mapping has been done by the plane-table method. With experienced topographers, many being former Geological Survey men, more than 18 000 sq. miles of territory have been mapped on scales of 5 000 and 10 000 ft. to the inch, and almost 1 000 sq. miles on the much larger scale of 1 000 ft. to the inch. A contour interval of 100 ft. was adopted for the small scale maps, and intervals of 20, 10, and 5 ft. for those of larger scale.

As a result of these extended surveys, the Department of Water and Power of the City of Los Angeles has constructed a large relief map of all this territory. On it may be delineated practically every route worthy of consideration for the proposed aqueduct.

#### BLYTHE ROUTE

A route originating 15 or 20 miles above Blythe, Calif., is the one favored by Mr. Mulholland. This route has many attractive features, and most of the construction involved can be done with little difficulty. It has been surveyed and examined in greater detail than the others.

Commencing with an intake approximately due east from Los Angeles, and at practically the nearest point on the river to the city, it skirts the southern end of the Maria Mountains in Riverside County, California, for a distance of from 10 to 15 miles. Then, by successive lifts and grade conduits, alternately, the line would be carried to the divide between the Colorado River Basin and the Coachella Valley of California. This divide is locally known as Shaver's Summit.

The total difference in elevation to be overcome in reaching Shaver's Summit is about 1 400 ft., to which must be added friction head. This would be accomplished in the first 75 miles of aqueduct. In order to overcome this difference in head with the least construction and operating difficulties, the lifting will be done in five stages. From Shaver's Summit to the end of the route, no further pumping will be required.

Between Shaver's Summit and Los Angeles, it will be necessary to construct approximately 35 miles of concrete-lined tunnels along the southwesterly face of the Little San Bernardino Mountains. There will also be a long tunnel under San Geronio Pass, varying from 13. to 27 miles in length, depending on its exact location, as yet not fully determined. From its westerly portal, a grade conduit and tunnels will complete the line to Los Angeles.

Along the Colorado River and parallel with the easterly part of this route are extensive gravel deposits, from which, it is believed, a sufficient quantity of clear water for the first few years of operation of the aqueduct can be obtained, either by constructing a large infiltration channel below the water-plane, or by pumping from wells suitably placed, or by both.

The adequacy of these gravels as a preliminary source of supply is to be thoroughly tested by pumping from a 2-mile section of full-sized infiltration canal, and from wells drilled at various points along the river front. About three-fourths of the length of the canal has been excavated to date (1927), and twelve wells have been drilled to depths varying from 60 to 200 ft.

As a result of the construction of a high dam either at Black or Boulder Canyons, it is believed that when a greater supply is needed, the river will be sufficiently desilted at the proposed point of intake to permit of its being pumped directly into the aqueduct. If, however, this is not the case, it can readily be made clear and potable by the usual methods of mechanical filtration.

#### BLACK CANYON ROUTE

A route originating at the Black Canyon Dam site has been surveyed in some detail. It is about 85 miles longer than the Blythe route, and involves greater construction difficulties. It also requires that the proposed Boulder Canyon Dam be constructed at the alternative Black Canyon site. As yet, the final location for this dam has not been definitely determined.

All lifts along this route would be near Black Canyon, and the corresponding total head would be greater than that required on the Blythe route. However, considerable return power could be generated at the westerly end of the aqueduct, making the net power consumed in pumping somewhat less than on the preceding route.

One inverted siphon, 13 miles in length, would be required. If this were constructed as a steel pressure line at the ground surface, it would be under a maximum head of 660 ft. If constructed as a tunnel with shafts, the head of course, would be greater. The advisability of a tunnel siphon is questionable, because of the volcanic character of the rock formation. The cost of this route would be materially higher than that of the Blythe route.

#### ROUTES FOR GRAVITY SUPPLY

In addition to the routes just described, two gravity routes have been suggested by other engineers. One has its point of intake about 110 miles up stream from the Boulder Canyon Dam site, and the other leaves the Colorado River a few miles below its junction with the San Juan, in Utah.

The former requires a dam at Bridge Canyon about 825 ft. in height above its foundation, in order to divert water into its aqueduct. Such a dam would create a reservoir storage of 6 200 000 acre-ft., and this reservoir would have to remain full at all times. The route would be 370 miles in length, including 170 miles of tunnels, with one tunnel of 71 miles, and another of 80 miles. An inverted siphon across the Colorado River near Topock, Calif., having a length of 12 miles and a maximum head of 1 300 ft. would also be necessary. This siphon would have to be constructed as a multi-barrel structure, in order to reduce the thickness of steel plate. If this route were adopted, an additional dam at the Glenn Canyon Dam site near Lee's Ferry, Ariz., would be required before many years had elapsed, to be utilized in postponing the time when the Bridge Canyon Reservoir would become filled with silt.

The other suggested gravity route would be more than 750 miles in length, and contain an even greater mileage of tunnels than the one described. It would remain on the northerly and westerly side of the Colorado River throughout its entire length. It is also proposed that this route be used for service other than domestic water supply in the States of Utah, Nevada, and California.

Sufficient investigation has been made of both of these gravity routes to show not only that they would be extremely expensive to construct, but that the time element would delay the delivery of water to the coast cities of Southern California so long as to make it impracticable as a municipal or metropolitan water project. Both routes contain power recovery features, which would offset, in part, their great cost. At the Bridge Canyon Dam site, in particular, field investigations and measurements create a doubt as to the advisability of constructing a dam to a greater height than the top of the exposed igneous rock, or 630 ft. above the low-water stage of the river. This would reduce the capacity of the reservoir to 3 100 000 acre-ft., and thereby greatly shorten its useful life as a de-silting medium.

#### ECONOMIES AND COSTS

All possible modifications of location, gradient, or lift, along the non-gravity routes have been under survey. Before the final determination of the particular route to be constructed is made, the economics of the situation require that much thought be given to many complex elements. Among them may be mentioned the following: The length of construction period, in years; the estimated cost of the proposed route completed; the cost as possibly modified by the omission of certain structures, such as units of pumping plants and force mains, which do not have to be constructed to full capacity at the start; the time factor introduced in the construction of the longest or most difficult tunnel, and the number and depths of shafts required; the number of lifts to be installed, and the lengths, sizes, and number of force mains comprising these lifts; the effective head available for return power; the cost of installing pumping plants, power plants, force mains, and pen-stocks; and the annual charges and pumping costs to be met in operating the routes under study.

The estimated cost of any of the several routes will vary with the hydraulic gradient selected. Those with flatter slopes, and correspondingly reduced velocity of water with increased cross-section, obviously will cost more to build. The cost of operating the pumping plants, on the other hand, will decrease with a reduction in the hydraulic gradient; consequently, these latter costs must be balanced in each case against interest charges on the proposed construction cost.

In operating an aqueduct of this character, the main item of cost is that of the power necessary for pumping. To date (1927), this cost has not been fixed, although for the purpose of carrying on economic studies, it has been assumed that power will be available at the rate of 3 mills per kw-hr. This is an estimated price for which power can be sold at the switchboard of a plant situated either at the Boulder or Black Canyon Dam sites, with a dam constructed 600 ft. in height above the low-water level of the river. In all studies due credit is given to an estimated possible income derived from the sale of return power at the westerly end of the proposed aqueduct, wherever head is available for that purpose.

As to the quantity of water required on the completion of the aqueduct project, studies have been made regarding the rate of growth of the population of all such cities of Southern California as may reasonably be expected to participate in the benefits. Their domestic needs have been carefully studied, and after deducting their present supply, the deficiencies have been assumed as being taken from the Colorado River.

The cost of pumping this water, both annually and in total throughout the years, together with the interest charges and installments of principal that will have to be borne by the population to be served, has been computed as carefully as such data can be. The resulting figures are being applied to each proposed route as the field information becomes available.

#### AQUEDUCTS AND DAMS

Various types of aqueduct construction are proposed. The quantity of water ultimately to be diverted is 1 500 cu. ft. per sec. When on hydraulic grade the line will be in excavation and completely covered throughout its length. When below hydraulic grade it will be either steel or reinforced concrete pipe, with possibly a pressure tunnel under San Gorgonio Pass. All tunnels will be lined with concrete.

The type of construction proposed for grade conduits is similar to that used on the Catskill Aqueduct. Where the nature of the ground surface makes it advisable to dip below the hydraulic grade and locate under light pressure, a reinforced concrete, hydro-static chord type similar to the 18-ft. conduit of the Ontario Power Company may be adopted. Under heavier pressure, steel pipe lines will be used. Due to the frequency of cloudbursts on the desert area to be traversed, the adoption of either an open conduit or a so-called cut-and-cover section blocking cross-drainage is not considered advisable. Pumping plants, pressure mains, and inverted siphons will be constructed in units as required.

Owing to the steepness of the slopes prevailing in the coastal plain of Southern California, there are few large reservoir sites available for regulating and distributing purposes at that end. The City of Pasadena has a proposed reservoir in San Gabriel Canyon, near Azusa, Calif., which, if constructed, would store 65 000 acre-ft. of water. The Los Angeles County Flood Control District also contemplates the construction of a reservoir near San Dimas, Calif., in what is known as the Puddingstone Reservoir site. It would be capable of storing at least 16 000 acre-ft., in addition to that required for flood-control purposes. Both these proposed reservoirs are situated at elevations which would make them practical for storage and distributing purposes, and all studies made thus far, contemplate maintaining the grade line at such elevation as to make use of either, if available.

Taking all these elements into consideration, the economics of the situation dictate that the route, gradients, and pumping lift to be adopted, be such as to place the least burden on the population to be served. Recognition must be given to the fact that the cities of Southern California are now growing rapidly, and will continue to grow at a rate which may become even faster.

## POWER REQUIREMENTS

In conclusion, the construction of any non-gravity aqueduct from the Colorado River to Los Angeles and neighboring cities, is predicated on the utilization of a large block of power. The only source which could furnish power in a sufficient quantity and at a cost not to be prohibitive, is the Colorado River. In order to generate this power, it would be necessary to construct a high dam on the river. The most favorable location for such a dam is either at Boulder Canyon or Black Canyon.

The investigations outlined in this paper have been made under the general supervision of William Mulholland, M. Am. Soc. C. E., Chief Engineer and General Manager, and the writer as Assistant Chief Engineer and General Manager of the Bureau of Water-Works and Supply of the City of Los Angeles. E. A. Bayley, M. Am. Soc. C. E., was in full charge of all field engineering.

## TRANS-MOUNTAIN DIVERSIONS IN COLORADO

BY ROBERT FOLLANSBEE,\* M. AM. SOC. C. E.

## PRESENT DEVELOPMENT

More than one-half the 103 658 sq. miles comprising the area of Colorado are within the Rocky Mountain region. The eastern part of the State lies within the province of the Great Plains, which extend from the front range of the Rockies to the Missouri River. Irrigation has been practiced in this region for many years, and the area of irrigable land is limited only by the water supply. The sources of this supply are the South Platte and Arkansas Rivers and their numerous tributaries, which rise on the eastern slope of the Rocky Mountains. With the present supply the limit of irrigation on the plains has almost been reached (except for the increased re-use of return seepage water).

In the mountainous region, except for certain relatively small areas, the water supply is in excess of that required by the irrigable lands. This situation has led water users to divert water from that region to the head-waters of the streams on the eastern slope. Table 1 summarizes the description of these diversions.

It will be noted from Table 1 that with the exception of the Laramie-Poudre Tunnel, which is 11 306 ft. long, all the diversions are made by relatively short open ditches at high elevations, and intercept the run-off from small areas.

## FUTURE DEVELOPMENT

The eleven developments made to date (1927) represent practically the limit of trans-mountain diversions by the relatively inexpensive open ditches, except for the proposed extension of Grand River Ditch. Additional developments must be of greater magnitude and expense, and be made by tunnels and collection ditches leading to them.

The need for additional water on the eastern slope has led water users to propose development from the Fraser, Williams, Blue, and Eagle Rivers and the Fryingpan Creek Basin, the only areas situated so that diversions from them to the eastern slope can be seriously considered for many years to come. Of these, the chief are the Fraser and Blue River diversions. They are on a scale so large, that they can only be undertaken by a municipality like Denver, where the economic phase of the question is not so much a governing factor as the necessity for obtaining additional water to provide for the city's future needs.

It, therefore, appears entirely probable that when these projects are finally undertaken and carried to completion, the systems will be so planned and constructed that they will collect about 80% of the available water. In fact, the city's engineers charged with planning its future water supply are con-

templating an efficiency of 90 per cent. To obtain this high efficiency, the collection ditches in earth and loose rock must be lined, and drainage ditches must be built along the upper side to collect the surface run-off and carry it to the cross-drainage channels which will empty into the main ditch. Also, provision must be made to clean the snow from the ditches by machines, early in the spring.

Judging from the experience gained from the operation of the Grand River and Skyline Ditches, it will be possible to exclude, during the winter months, the run-off from the intercepted streams entering the main ditches, and thus prevent the formation of any great quantity of ice. Also, it may be necessary to cover some parts of the ditches. On the capacities of the tunnels and ditches will depend the storage required. Ditches on southern slopes will obtain water fully two weeks earlier than those on northern slopes; the peak flow will be higher and its subsidence more rapid. Open ditches at lower elevations will encounter less slide rock and will be subject to less danger from heaving, due to the less severe frost action.

The period of the year for which diversion can be made, is taken as that from April 1 to September 30 because that is the average period during which the proposed diversions (except the relatively small one from Fryingpan Creek) can be made without interference with the right of the hydro-electric plant at Shoshone, on the Colorado River. In determining the available water supply no consideration has been given the conflict with water rights immediately below the proposed diversions, as these must be acquired and extinguished.

*Fraser River.*—With the completion of the Moffat Water Tunnel, which parallels the railroad tunnel at a distance of 75 ft., and has an elevation of 9 300 ft. at its mid-point, the City of Denver has planned to construct a system to divert water to the South Platte Basin. From the west portal of the water tunnel, in NE.  $\frac{1}{4}$  Sec. 10, T. 25 N., R. 75 W., two collection ditches are to be constructed, one 27 miles long, reaching West St. Louis Creek, and the other, 9 miles long, reaching North Ranch Creek. This system will intercept the run-off from 107 sq. miles of drainage area, ranging in altitude from 9 300 to 12 500 ft. From the records of the Fraser River near West Portal (1911-26), the unit run-off for the period from April 1 to September 30 is estimated as 1 060 acre-ft. per sq. mile, or 113 000 acre-ft. from the entire area intercepted. With an efficiency of 80% the mean annual diversion would be 90 400 acre-ft. A study of the 30-year record of the Colorado River near Palisades indicates that the mean for that period is 94% of the 16-year mean (1911-26). On this basis the mean annual diversion would be reduced to 85 000 acre-ft.

The annual variation in the proposed diversion is shown by Table 2, based on the annual percentages for Fraser River, near West Portal, and the mean diversion of 90 400 acre-ft. It will be noted from Table 2 that in the lowest year of the 16-year period, the diversion would have been 63 200 acre-ft.

To carry the maximum discharge of the wettest year, a tunnel capacity of 3 100 sec.-ft. would be required. However, it is possible to obtain some

storage above the proposed diversions, and this would reduce the required tunnel capacity. A capacity of 1 000 sec-ft. would have required annual storage during the past 16 years, as follows:

Year.	Acre-feet.	Year.	Acre-feet.
1914.....	22 200	1921.....	15 400
1915.....	25 000	1923.....	3 880
1917.....	3 990	1924.....	3 990
1918.....	26 900	1926.....	3 590

*Williams River.*—Several surveys have been made to investigate the diversion of water from Williams River to Clear Creek in the South Platte Basin. The most comprehensive survey has been made by the City of Denver, which proposes to bore a tunnel 3 miles long at an altitude of 10 300 ft.\* The west portal will be on Bobtail Creek, a tributary of Williams River, and the east portal on the West Fork of Clear Creek. From the west portal, one collection ditch will extend to an unnamed creek beyond McQueary Creek, a distance of 4 miles, and another ditch will extend to the South Fork of the Williams River, a distance of 18 miles. These ditches will intercept the run-off from 29 sq. miles of drainage area, ranging in altitude from 10 400 to 12 500 ft. No records of the Upper Williams River are available, but by a comparison with the Fraser River records, the unit run-off above 10 400 ft. from April 1 to September 30, inclusive, is estimated as 1 100 acre-ft., or 32 000 acre-ft. for the entire 29 sq. miles. With an efficiency of 80%, the mean annual diversion would be 25 600 acre-ft. A tunnel capacity of 600 sec-ft. will be required without storage on the western slope to divert this quantity of water.

A study of the Palisades records indicates that the 30-year mean is 94% of the 16-year mean (1911-26). On this basis, the mean annual diversion would be reduced to 24 000 acre-ft.

\* This is about the lowest altitude believed to be feasible for a water tunnel, as the slopes on both sides of the Continental Divide are such that a tunnel at 9 300 ft., the altitude of the Fraser River diversion, would be 11 miles long.

*Blue River.*—This basin is so situated with reference to the eastern slope that a number of possible diversions present themselves. Surveys have been made by the City of Denver for diversions at elevations of 10 300, 9 500, 9 112, and 8 842 ft.; and the writer has made a preliminary study for one at an elevation of 9 800 ft. Table 3 shows the possibilities at each elevation proposed.

TABLE 3.—PROPOSED DIVERSIONS FROM BLUE RIVER AT VARIOUS ELEVATIONS.

DIVERSION.		Elevation, in feet.	LENGTH OF CONDUIT.		Area intercepted, in square miles.	Mean annual diversion (80 %), in acre-feet.

Blue River.....	North Fork, South Platte River.....	9 112	18.9	14	293	189 000
" ".....	North Fork, South Platte River.....	8 842	22.8	1	328	197 000

The quantity of water that can be diverted will depend on the length of the collection ditches built from the receiving portal of the tunnel along the mountain sides. Since the diversion of a given quantity of water requires a shorter collection ditch as the elevation of the tunnel is decreased, it follows that, for the same length of collection ditch, the quantity of water that can be diverted, will increase with the decrease in elevation.

In Table 3 it will be noted that for 26 miles of ditches the diversions would increase from 28 000 to 96 000 acre-ft., with an increase in tunnel length from 3 to 12.9 miles. The projects requiring tunnel lengths of 18.9 and 22.8 miles make available such large diversions that a study showing those available with ditches 26 miles long has not been made. Since the City of Denver is the only water user that can afford to make a diversion from Blue River, at least within the period of time for which a forecast of future use can safely be made, and since a tunnel 12.9 miles long will yield a quantity of water sufficient for Denver's needs for the same period, and is within the realm of present-day engineering practice, the diversion of 96 000 acre-ft. at an elevation of 9 500 ft. has been selected for the purpose of this paper.

The west portal would probably be on Swan River, in SE.  $\frac{1}{4}$  Sec. 15, T. 6 S., R. 77 W., 1 mile below Tiger. Collection ditches extending from the North Fork of the Snake River on the north to North Barton Creek on the south would have a total length of 26 miles and intercept the run-off from 181 sq. miles of drainage area ranging in elevation from 9 500 to 13 500 ft. Stream-gauging records are available for the Blue River, at Dillon (1911-26) and for the Snake River, at Dillon (1911-19). For the nine-year period (1911-19), the mean run-off from April 1 to September 30 is 148 000 acre-ft., or 676 acre-ft. per sq. mile for 219 sq. miles, ranging in elevation from 8 850 to 13 500 ft. As the run-off increases with elevation, the unit run-off for the

area above 9 500 ft. will be slightly greater, and has been taken as 718 acre-ft. This gives a total run-off of 120 000 acre-ft. above the 181 sq. miles lying above the collection ditches. With an efficiency of 80%, the mean annual diversion will be 96 000 acre-ft.

A study of the 30-year record of the Colorado River near Palisades indicates that the mean for that period is 95% of that for the 9-year period covered by the Blue and Snake River records. On this basis the mean annual diversion from Blue River would be 91 200 acre-ft.

The variation in run-off available for diversion from April 1 to September 30 each year under the project, at 9 500 ft. elevation, is shown by Table 4 which is based on a mean run-off of 96 000 acre-ft., and an annual percentage determined from the run-off from April to September each year at the gauging station on Blue River, at Dillon.

TABLE 4.—ANNUAL DIVERSION FROM BLUE RIVER BASIN.

Year.	Run-off above diversion points, in acre-feet.	Percentage of mean.
1911.....	83 500	86
1912.....	115 000	120
1913.....	86 500	90
1914.....	134 000	140
1915.....	82 500	86
1916.....	85 500	89
1917.....	106 000	111
1918.....	111 000	116
1919.....	69 000	72
1920.....	87 300	91
1921.....	121 000	126
1922.....	72 000	75
1923.....	111 000	116
1924.....	87 200	91
1925.....	72 000	75
1926.....	119 000	124
Mean.....	96 000	....

It will be noted that in the lowest year of the 16-year period, the diversion would have been 69 000 acre-ft.

The maximum discharge at the tunnel site during the years of record was 1 880 sec-ft. With a tunnel capacity of 1 000 sec-ft., the following storage would have been required to care for the excess run-off:

Year.	Acre-feet.
1914 .....	19 500
1917 .....	6 480
1918 .....	17 000
1921 .....	10 700*
1923 .....	2 050
1924 .....	1 930
1926 .....	6 740

*Eagle River.*—At Tennessee Pass, which separates the Eagle and Arkansas Drainage Basins, an opportunity is afforded for the diversion of water from Eagle River. A tunnel at an elevation of 10 200 ft. would be 2 miles long

and at 9 800 ft., 6 miles long. Since the slope of Eagle River Basin prevents the interception of any area comparable in size with the areas in the Fraser and Blue Drainage Basins, it is evident that for the quantity of water available, a length of tunnel greater than 2 miles would not be warranted. With the tunnel at 10 200 ft. elevation and 15 miles of collection ditches reaching Bennett Creek on the west side, and East Fork on the east, an area of 30 sq. miles will be intercepted, ranging in elevation from 10 200 to 13 000 ft. Records of Eagle River at Redcliffe from 1911 to 1925 show the mean run-off from April 1 to September 30 to be 594 acre-ft. per sq. mile. For the area above 10 200 ft. elevation, the unit run-off is estimated as 700 acre-ft. per sq. mile, or 21 000 acre-ft. for the 30 sq. miles intercepted. With an operating efficiency of 80%, 16 800 acre-ft. could be diverted.

A low divide between Eagle River and Tenmile Creek Drainage Basins makes possible a diversion at 10 900 ft. by a tunnel  $\frac{1}{2}$  mile long.\* A ditch,  $3\frac{1}{2}$  miles long, on the west side reaching Searles Gulch, and one,  $6\frac{1}{2}$  miles long, on the east side, reaching Mayflower Gulch, will intercept an area of 20 sq. miles, ranging in elevation from 10 900 to 13 500 ft. Records of Tenmile Creek, at Dillon, from 1911 to 1919, show the mean run-off from April 1 to September 30 to be 872 acre-ft. per sq. mile. For the area above 10 900 ft., the unit run-off is estimated as 1 000 acre-ft. per sq. mile, or 20 000 acre-ft. for the entire area intercepted. With an efficiency of 80%, 16 000 acre-ft. could be diverted. The diversion from Tenmile Creek would be made to the East Side Collection Ditch of the Eagle River System.

The annual variation in the combined diversions proposed from the Eagle and Tenmile Basins is shown in Table 5, which is based on a mean discharge of 32 800 acre-ft. adjusted according to the variation at the Eagle and Tenmile Gauging Stations.

TABLE 5.—ANNUAL DIVERSION FROM EAGLE RIVER AND TENMILE CREEK.

Year.	Run-off above diversion points, in acre-feet.	Percentage of mean.
1911.....	39 000	119
1912.....	42 600	130
1913.....	25 600	78
1914.....	41 300	126
1915.....	23 300	71
1916.....	31 800	97
1917.....	33 900	103
1918.....	41 300	126
1919.....	24 300	74
1920.....	33 400	102
1921.....	41 300	126
1922.....	23 000	70
1923.....	34 400	105
1924.....	27 600	84
1925.....	22 700	69
Mean.....	32 800	.....

It will be noted in Table 5 that in the lowest year of the 15-year period, the diversion would have been 22 700 acre-ft. Without storage on the western slope, a tunnel capacity of 700 sec.-ft. would be required.

\* Lowering the elevation of the tunnel 100 ft. would increase its length to  $1\frac{1}{2}$  miles.

From the Palisades records it appears that the 29-year mean (1897-1925) is 93% of the 15-year mean (1911-1925), and, on this basis, the mean run-off available for diversion would be 30 500 acre-ft.

*Fryingpan Creek.*—Ivanhoe Tunnel, in Sec. 13, T. 9 S., R. 82 W., 11 miles west of Leadville, on the abandoned Colorado Midland Railway, affords an opportunity to divert water from Fryingpan Creek to Lake Fork, a tributary of the Arkansas River. The tunnel, which is at an altitude of 10 950 ft., is 2 miles long, with an eastward slope of 15 ft. per 1 000. Near the west portal, lies Lake Ivanhoe which can be converted into a reservoir of 1920 acre-ft. capacity by a 30-ft. dam at each end. A collection ditch, 14 miles long, heading in the main fork of Fryingpan Creek, would intercept the run-off from 12 sq. miles of drainage area, ranging in altitude from 11 000 to 13 500 ft. Records of Fryingpan Creek at Norrie (Elevation 8 440), from 1911 to 1916, show the mean run-off from April 1 to September 30 to be 1 040 acre-ft. per sq. mile. For the area above 11 000 ft., the unit run-off is estimated to be 1 300 acre-ft. per sq. mile, or 16 000 acre-ft. for the 12 sq. miles intercepted. At an efficiency of 80% the annual diversion would be 12 800 acre-ft. Irrigation interests in the Arkansas Valley have started construction work on this diversion.

*Summary of Future Development.*—The developments here described are summarized in Table 6.

TABLE 6.—SUMMARY OF FUTURE DEVELOPMENT.

\* Including diversion from Tenmile Creek.

† Ivanhoe Tunnel on abandoned Colorado Midland Railway.

From the magnitude of the work involved, it will probably be many years before these diversions are completely developed.

*Effect of Diversions on the Flow of the Colorado River.*—To determine the effect of the possible diversions on the flow of the Colorado River at various points, it is necessary to compute the monthly quantities to be diverted. For that purpose, the period, 1911-26, in so far as available for each stream, was selected, and the monthly percentages for the entire discharge from April 1 to September 30 were determined from the records on each stream. These percentages were applied to the mean diversions for each project.

TABLE 7.—MEAN MONTHLY DISCHARGE OF PROPOSED DIVERSIONS.

Drainage basin.	DISCHARGE, IN ACRE-FEET.					
	April.	May.	June.	July.	August.	September.
Fraser River.....	2 710	17 200	40 700	18 100	7 220	4 520
Williams River.....	1 020	4 850	11 000	5 370	2 050	1 280
Blue River.....	3 840	19 200	36 500	21 100	9 600	5 760
Eagle River.....	1 970	9 520	12 500	5 240	2 290	1 300
Fryingpan Creek.....	640	3 070	5 880	2 300	900	510
Total.....	10 200	53 800	106 000	52 100	22 100	13 400

The effect of these diversions on the flow of the Colorado River is shown by deducting from the mean monthly recorded flow for the period, 1911 to 1926, in so far as it is available, the computed quantities given in Table 7, and expressing the differences as percentages of the recorded flow. These are given in Table 8 for each principal gauging station above the Green River, and for Yuma, Ariz.

TABLE 8.—DISCHARGE MODIFIED BY PROPOSED DIVERSIONS EXPRESSED AS PERCENTAGES OF MEASURED DISCHARGE.

Gauging station.	April.	May.	June.	July.	August.	September.
Kremmling, Colo.*.....	91	85	82	80	78	77
Glenwood Springs, Colo.†.....	93	90	88	85	84	85
Fallsades, Colo.‡.....	96	94	93	91	91	92
Cisco, Utah.....	98	97	95	94	94	94
Yuma, Ariz.....	99.3	98.0	97.8	98.0	98.0	97.6

\* Above diversions from Eagle River and Fryingpan Creek.

† Above diversions from Fryingpan Creek.

‡ Above diversions for Grand Valley.

The effect of the proposed diversions on the flow of the Colorado River will be a maximum at the Kremmling Station and will decrease at points farther down stream where the discharge is successively greater. From the substantial uniformity of annual variation in discharge throughout the Upper Basin, it is believed that the percentages in Table 8 will apply each year.

## DISCUSSION

A. LINCOLN FELLOWS,\* Esq. (by letter).—Mr. Debler has furnished a valuable contribution to the literature on trans-mountain diversions which the writer takes pleasure in endorsing as generally correct. However, in the interest of historical accuracy he desires to supplement the statement made with reference to the commencement of work on the Gunnison Tunnel. The author correctly states that the plan was conceived in 1890 by Mr. L. C. Lauzon, but the impression is given to the casual reader that the State of Colorado led the way in commencing work on the construction of the tunnel. This is true in so far as actual construction on a State tunnel was concerned; but, in reality, the U. S. Geological Survey was first, by some months. That organization set apart funds for the commencement of surveys in the latter part of 1900, on the recommendation of F. H. Newell, M. Am. Soc. C. E., and the writer. The appropriation by the State Legislature followed in 1901, five or six months later. Construction of a tunnel by the State was begun after the first preliminary survey was completed, before the final surveys and reports were made, and contrary to the advice of the writer. This State tunnel was entirely distinct and located at a considerable distance from the Government location. It was eventually abandoned completely.

Some very interesting trans-mountain diversions have been made in Wyoming, several of them dating back many years. Indeed, Wyoming has been a pioneer in making such diversions. The writer also calls attention to a notable project in North Dakota—the suggested diversion of the Missouri River into the Red River drainage basin, or, in other words, the proposed diversion from a stream discharging into the Gulf of Mexico to the Hudson Bay drainage basin. The State Irrigation Engineer of North Dakota, Robert E. Kennedy, has prepared preliminary reports regarding this project.

RALPH BENNETT,† M. Am. Soc. C. E. (by letter).—Only those routes for the proposed Los Angeles-Colorado River Canal that lie north of the Imperial Valley, are mentioned specifically by Mr. Van Norman.

There are also a number of possible routes in which the water would be diverted through the Imperial Canals and carried in them for varying distances before entering the plants that would lift the water over the range (see Fig. 3).

Of these, the most southerly, and, therefore, the ones of particular interest to San Diego, Calif., would divert from the existing Imperial System in the vicinity of Dixieland and would rise to the crest at an elevation of nearly 4 000 ft. above sea level in less than 40 miles. Even with power at 0.5 cent per kw-hr., water so delivered would cost San Diego less than that secured by the present storage system. As this diversion would deliver into coastal streams which flow into large existing reservoirs of that city, it could be put in without reference to Colorado River storage and the plant could be operated only when excess flow was available.

\* Irrig. Engr., Bureau of Public Roads, U. S. Dept. of Agriculture, Denver, Colo.

† Cons. Engr., Los Angeles, Calif.

The next northerly possibility is a diversion from the Imperial System in the vicinity of Westmoreland into a conduit running west through the Borego Valley and crossing under the summit in a long tunnel under the Town of Julian. This route would vastly supplement the water supply in the vicinity of Oceanside, but would not reach the urban district around Los Angeles to advantage. It would also be deficient in storage.

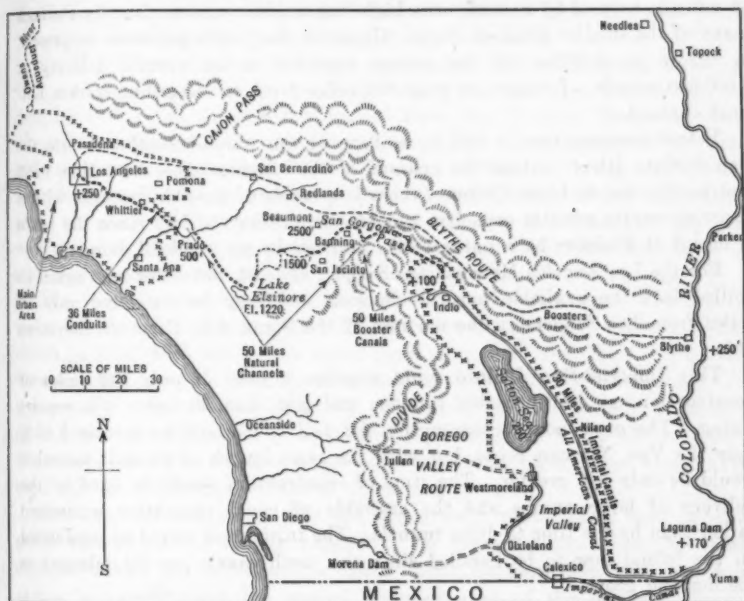

FIG. 3.—MAP SHOWING LOS ANGELES-COLORADO RIVER AQUEDUCT.

The most northerly of the Imperial Valley routes would lie through the Imperial and Coachella Valleys to a regulating basin west of Indio at about Elevation +100. This point would be almost 130 miles from Laguna Dam across a smooth unbroken plain of soft soils well suited to the excavation of an earth canal. As the revised crest at Laguna will be at least as high as Elevation +170, there would be ample fall available.

In reaching this point, the All-American Canal and its extension northwesterly would serve more than 500 000 acres of land, and incidental to that service the water would be completely desilted before the first pumping plant was reached. From this terminal reservoir of the Imperial System the water would be lifted by boosters through a series of canals lying in the more elevated portions of the valley until it passed over the Beaumont crest of San Geronimo Pass into the coastal areas. These canals would not require tunnels or extensive rock excavation.

During the first half of the development period, or until at least a flow of 1000 sec.-ft. was in actual use, even the summit lift would be without

reduction by tunnel. For these, sections could be located so that power recovery plants could be placed cheaply on the westerly slopes and return fully one-half the gross power. This run in high-level canals and pumping lines would not exceed 50 miles in total length.

The Beaumont summit is at Elevation 2 500 and is 80 miles in an air line from Los Angeles. In the route suggested by Mr. Van Norman this 80 miles is covered by a continuous high-line conduit passing directly through many of the smaller cities en route. However, that route possesses no present or future possibilities for the storage essential to the certain delivery of 1 000 000 acre-ft. of water per year 270 miles from its diversion from a natural channel.

Better economy can be had by spilling at the summit southwest into the San Jacinto River. Along the channel of this stream below Elevation 1 500 and continuing to Lake Elsinore, there is a series of possible storages with a great aggregate possible capacity, and of extraordinary safety since the basin is closed at Elsinore by a natural dike and not by an artificial dam.

For the Los Angeles Metropolitan Supply, at least, the water may again be spilled into the available natural channels and may be recovered only 36 miles from Los Angeles in the narrows of the Santa Ana River at Elevation 500.

This Imperial-San Jacinto route requires a total of only 216 miles of construction, no indispensable tunnels, and less than 50 miles will require lining. The gross power consumption for full flow would be increased 25% over the Van Norman route, but with the same length of summit tunnel it would be only 5% greater. The time of construction would be fixed by the delivery of large pumps and the assembly of canal excavation equipment rather than by the time to drive tunnels. The initial cost would be predicated on the initial flow to be handled since the earth canals can be enlarged as the demand grows.

If, at some later date, a full gravity system is substituted, the loss of fixed investment would be limited to the abandoned pumping plants and such high-level canals as do not fit the proposed new elevation. The earth canals in the Imperial Valley would be released to purely irrigation use.

Tentative estimates indicate that the cost along this line would not be more than one-half or one-third that along the Blythe route; and here, again, as in the San Diego line, the possible coastal or delivery end storage would be so great that the line could be operated regardless of storage conditions on the Colorado River. Indeed it could be operated during some years of light load with off-peak power from the existing systems, or the 70 000 kw. which may be made available from the All-American Canal without reference to the completion of the power plant at the Boulder Canyon Dam.

B. F. JAKOBSEN,\* M. AM. SOC. C. E. (by letter).—Mr. Van Norman states that a careful investigation shows that Los Angeles will reach the limit of its water supply within ten years, but he does not give any authority for this statement. Careful engineering investigations made by competent

\* Cons. Engr. (La Rue & Jakobsen), Los Angeles, Calif.

engineers, such as Thomas H. Means, M. Am. Soc. C. E., Paul Bailey, M. Am. Soc. C. E., and others, show that additional water supply can be obtained from Owens Valley and Mono Basin in sufficient quantity to justify the building of another aqueduct from Owens Valley with a capacity of about 450 sec.-ft., and that the power which can be developed would pay for this additional aqueduct. This water is ideal in quality for domestic use, and would supply a population of about 4 000 000. It will most likely be much more than "ten years" before this population is reached.

Mr. Van Norman refers to a large infiltration canal. There will be about 8 000 acre-ft. of mud to be removed each year from the 1 500 sec.-ft. of flow, for which Los Angeles has applied from the Colorado River. Assume the width of the available river area to be 528 ft., or 0.1 mile, or an area of 64 acres per mile length of infiltration canal. If the silt is deposited in the filter to a depth of 2 ft. and there are 25% voids, 250 miles of infiltration canal per year will be needed. This does not look very practical, and the writer doubts whether the usual methods of mechanical filtration, which is suggested as an alternative, will work much better.

The storage capacity of Bridge Canyon Gravity Aqueduct diversion is given by Mr. Van Norman as 6 200 000 acre-ft., and he states that this would be filled with silt before many years, and that, therefore, if this site were selected, it would require an additional dam within a short time. At this point the river carries about 100 000 acre-ft. of silt annually, so that if all the silt were deposited, it would still take 62 years to fill the reservoir. Long before the silt problem would become serious, other dams would have been built in the natural course of developing the river.

Mr. Van Norman states that the two gravity routes have been investigated and found "extremely expensive" to construct, and that the time element needed for construction make them impracticable. In a recent article he stated\* that the annual pumping cost of the proposed project will be \$8 400 000. Capitalizing this at 4.5% per year gives \$187 000 000. If Mr. Van Norman will add this to the cost of the proposed pumping plan, the writer believes he may find it difficult to maintain his assertion that the gravity routes will be "extremely expensive."

Doubt has been expressed by Mr. Van Norman whether a dam higher than 630 ft. above the low-water stage of the river can be safely built at the Bridge Canyon site. A geological report described the rock above the exposed igneous rock as hard quartzitic sandstone. It might be well to leave this an open question until decision can be made on the most competent geological and engineering advice.

Much value would be added to this paper if Mr. Van Norman would give the detailed cost data which he states have been prepared. It would be especially interesting to compare the two proposed gravity routes with the proposed pumping scheme with its enormous annual pumping charges.

Mr. Van Norman states that the most favorable location for a power dam is at Boulder Canyon. A number of such sites have been described in a

\* *Engineering News-Record*, May 31, 1928, p. 853.

report\* by E. C. La Rue, M. Am. Soc. C. E., according to which it would be a serious mistake to construct the proposed Boulder Canyon Dam, since it does not fit into a general plan of development of the river, and would result in a waste of about 300 000 h.p. William Kelly, M. Am. Soc. C. E., while Chief Engineer for the Federal Power Commission, also investigated the proposed Boulder Canyon Dam and recommended against it.

Mr. Van Norman has failed to mention the opinions and ideas of competent engineers who differ with him. Some plan should be arranged which would receive the approval of a considerable number of competent engineers, and it should be understood that there is nothing final about the proposed plan.

PAUL M. ENTENMAN,† ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Van Norman's paper shows clearly that, of the routes surveyed for the Los Angeles-Colorado River Aqueduct, there are but two that deserve serious consideration—the Blythe route and the Black Canyon route. As the Black Canyon is predicated on the choice of a site for the construction of the proposed Boulder Dam (which may not be the one finally selected) the adoption of the Blythe route, or a route farther south, seems inevitable. This is apparent since it will be desirable to begin early construction of the aqueduct, whereas the approval of legislation authorizing the Boulder Canyon project may be delayed.

Mr. Van Norman states that investigations of the feasibility of the Blythe route as a project independent of the construction of the Boulder Dam, are being conducted. Without a high dam creating a reservoir that will act as a desilting basin, the problem of excluding the silt of the Colorado River from the aqueduct will be one of major importance.

The proposed intake is located 120 miles below the canyon, in the section of the river characterized by broad, fertile, deltaic plains. In this region, the river flows in a bed of its own alluvium. Logs of wells and other sub-surface explorations show that the alluvial deposit is of more or less uniform character for great depths. It is marked by extreme fineness of the constituent particles. Underground flow through this material is so slow that it is doubtful whether an infiltration basin of sufficient capacity to serve the aqueduct would be feasible, for irrespective of the porosity of the material in which the infiltration canal may be constructed, flow into the canal must be through the fine bed silts of the river.

The rate of underground flow, investigated with Hazen's well-known formula,‡ assuming  $d = 0.10$  mm., is found to be a velocity too low to serve an infiltration canal of reasonable dimensions.

The assumed value of  $d = 0.10$  mm. is larger than the effective size of the sand grains in the bed of the Colorado. Fortier and Blaney§ give a mechanical analysis of the deposits in the bed of the river from a number of samples; one, taken at the intake of the Palo Verde Canal, within five miles

of the site of the proposed intake for the Los Angeles Aqueduct, shows that 14.02% of the sample consisted of grains having diameters of 0.05 mm.\*

A theory that extensive strata of water-bearing gravels may be found below the silt and sand has considerable currency. The investigations of Fortier and Blaney show clearly that very little material that can be classified as coarse sand reaches the lower river.† The canyon section of the stream is an efficient grinding mill reducing boulders, gravel, and sand to a silt of which more than 50% is finer than Portland cement.

Occasional beds of gravel are found where *débris* cones at the mouths of washes debouch directly into the river; but even then gravel is not found in extended sheets. During floods, the river has sufficient velocity to transport any gravel or small boulders which may enter it from a wash; and successive floods cause a wide distribution of this *débris*. Such gravel beds as are found in the Colorado River occur in lenses or in long trains of coarse material in the buried channel of the stream.

As it is unlikely that an infiltration canal of sufficient capacity to serve the proposed Los Angeles Aqueduct will be feasible, the intake structure must include some desilting device. The most successful desilting structure on the Lower Colorado is the settling channel and sluice-way at Laguna Dam. A diversion weir raises the level of the river about 10 ft. The settling basin is 650 ft. long, with a cross-section 126 ft. wide at the top, 116 ft. at the bottom, and 18 ft. deep. At its down-stream end are three sluice-way openings, 33 ft. wide, controlled by Stoney roller gates. Water is skimmed from the surface of the settling channel through a gate with thirty-five 7½-ft. openings regulated by flash-boards.

Once a week, the sluice-gates are opened, and the silt which has accumulated in the settling channel is sluiced back into the river below the Laguna Dam. The settling channel is effective in removing all the bed silt and about 50% of the suspended silt in the river.‡

The site of the proposed intake for the Los Angeles Aqueduct is not favorable for the construction of a weir, but as all the water has to be pumped in any event, head for sluicing purposes could be developed with pumps. However, unless the fluctuations in discharge are to be controlled completely by the construction of the Boulder Canyon Reservoir, some form of diversion structure will be necessary. The experience of the Imperial Irrigation District with rock-fill dams across the Colorado shows that a much cheaper structure than the Laguna Dam, such as that closing the Bee River channel,§ will serve this purpose, provided there is ample spillway capacity to prevent overtopping.

The settling channel for the proposed aqueduct should be designed to reduce the velocity in this basin to less than ½ ft. per sec.; and the gates controlling the flow to the aqueduct should be of such capacity that only the surface water between 6 in. and 1 ft. in depth will be skimmed from the settling

channel. Some device other than flash-boards should provide regulation of flow. It is surely not beyond the ingenuity of engineers to design a skimming gate that will be tighter than a flash-board structure. At Laguna Dam, it has been found that some of the silt which enters the canal leaks through and around the flash-boards, and that more silt than is actually suspended in the surface water of the settling basin flows into the canal through the boards and by reason of vertical currents that form along the face of the regulating gates. Laboratory studies of the control of these vertical currents and of the design of a form of hinged gate that would replace the crude flash-boards is warranted for a project of the magnitude of the Los Angeles Aqueduct.

The quantity of silt carried by the Lower Colorado River varies with the discharge. At the lower end of the canyons 0.86%, by volume, is an average. When the aqueduct is operated to full capacity, this would mean transporting nearly 10 000 acre-ft. of silt each year. Unless this silt is removed at the intake, its deposition in storage reservoirs along the route of the aqueduct would rapidly diminish their capacity.

The silt should be removed at the river for another reason. Its abrasive nature is destructive of the working parts of pumps. More than 70% is silica, and its exceeding fineness permits its penetrating close spaces. An ordinary centrifugal pump will have its bearings ground out in a month's or six weeks' operation. Pumps are made with outboard bearings to meet this problem, but the runners and shell wear rapidly, especially when operated at high speeds and against high heads.

If the head for sluicing purposes is developed with pumps instead of with a diversion dam, such pumps would have to handle silty water. However, the lift would be comparatively low, and large-capacity, low-lift pumps of the propeller type have handled Colorado River water without excessive wear. That settling channels are completely successful for the removal of silt has been demonstrated on a small scale in the water-works plant at Calexico, Calif.

Any study of the silt problem of the Colorado as it affects a domestic supply for Los Angeles, as well as the irrigation projects in the lower river, emphasizes the importance of constructing some desilting structure in the canyons of the river. The most recent computations of the quantity of silt transported to the end of the canyon section are those of Fortier and Blaney who estimate that 137 000 acre-ft. reach the lower river annually.\* They conclude that: "The most feasible and economical means of solving the silt problem \* \* \* is to impound the river silt behind a high dam, such as is proposed at Boulder Canyon."

H. A. VAN NORMAN,† M. AM. SOC. C. E. (by letter).—The writer wishes to thank the discussers for the interest which they have shown in the proposed Los Angeles-Colorado River Aqueduct. Many of the ideas suggested are feasible under some one or more variations of the conditions of the problem which are not specifically defined.

However, several additional steps have been made toward the realization of this gigantic and needed improvement, two of which are worthy of mention.

\* Technical Bulletin No. 67, U. S. Bureau of Public Roads, p. 4.

† Asst. Chf. Engr., Dept. of Water, City of Los Angeles, Los Angeles, Calif.

The first step occurred on November 6, 1928, when eleven incorporated cities, in the Southern California Coastal Plain, signified their intention, by popular vote, of joining a Metropolitan Water District of Southern California for the purpose of procuring water from the Colorado River. The second great stride was the passing of the Swing-Johnson Bill on December 21, 1928. The significance of this Bill is that the Federal Government definitely decided its policy in the allocation of water from the Colorado River and made the first step toward development by the authorization of the construction of the Boulder Dam. The location of the first dam to be built on the river necessarily fixes a definite outline for future development. This eliminates one of the heretofore variable conditions in the plan of any Los Angeles-Colorado River Aqueduct.

The construction of a high dam at Black Canyon by the Federal Government, which will completely regulate the flow of the Colorado River and prevent the major portion of the silt from reaching any smaller reservoirs which may be built below it, allows the alternatives not mentioned in the paper, to be considered.

*Blythe-Parker Route.*—Under this condition, a dam approximately 80 ft. in height might be built at one of two favorable locations above Parker, Ariz. The first site is situated just below the junction of the Williams River and is about 12 miles above Parker. The other site is about 6 miles up stream from Parker. An 80-ft. dam at either place would create a reservoir of approximately 1 000 000 acre-ft., which would raise the water surface to Elevation 440 and re-desilt the water for the aqueduct. From a reservoir so created, a line could be built along the west side of the river to connect with the present Blythe route south of the infiltration gallery. An alternative would come down the river front to the north end of the Riverside Mountains where a pump lift would raise the water to Elevation 940. Thence, it would proceed westerly and southerly, via Grommet and Rice, Calif., tunneling through the Coxcomb Mountains, to a junction with the Blythe route, at an elevation of 1 300 ft., about 12 miles east of Shaver's Summit.

*Picacho Route.*—This proposed route originates in a reservoir about 30 miles up stream from Yuma, Ariz. The reservoir would be created by a dam of undetermined height to be built in a canyon of the Colorado River, about 3 miles below the old mining town of Picacho, Ariz., where the water surface has an elevation of 170 ft. It would have a capacity of from 1 000 000 to 2 000 000 acre-ft., depending on the height of the dam. Drillings are now (1929) being made to determine to what height it is feasible to construct a dam at this point. Enough power can be generated at the dam to lift the water to Elevation 500.

From the upper end of a pump lift at Elevation 500, the aqueduct pierces the Picacho Mountains in a tunnel approximately 14 miles long, with shallow shafts, to the east slope of the Salton Sea Basin. Thence, it continues north-westerly in conduit through smooth desert country along the eastern slope of the basin to a point east of Mecca, Calif., where there is a 10-mile stretch of short tunnels. Thence, the line proceeds in conduit to a point 6 miles north-east of Indio, Calif., where the water is lifted approximately 1 025 ft. to Elevation 1 250, continuing in conduit section to 1 mile west of Whitewater, Calif.,

where there is another pump lift of 275 ft. to an elevation of about 1500, at which point it joins the Blythe route, or a variation thereof. From this point the aqueduct follows the Blythe route under San Geronio Pass and to the Metropolitan Water District.

The Picacho route, if constructed, would be about 242 miles long from the Colorado River to a terminal reservoir at or near San Gabriel, Calif., and would require a total lift of approximately 1580 ft. This route throughout its length would be through accessible country, in the proximity of the Southern Pacific Railroad except at the point of diversion.

The statement by Mr. Jakobsen as to the ultimate life of the reservoir at Bridge Canyon is correct if one assumes 100 000 acre-ft. of silt per annum, and that the full volume is effective as a desilting medium; but if the figure of 137 000 acre-ft. of silt per annum, as given by Fortier and Blaney in their more recent studies, is used, and only a part of the volume of the reservoir is considered for silt storage, then the effective life of a reservoir at Bridge Canyon would be greatly reduced.

Mr. Jakobsen also states that by capitalizing the annual pumping cost which would have to be met on any of the pumping routes, at 4½% per year, the money value would be \$187 000 000. This would be nearly cut in half if he would use an interest rate of about 7 to 8%, in order to offset depreciation, operation, and maintenance charges on the excess length and cost of the gravity aqueduct with which he is making his comparison. It would be further reduced if consideration were given to the fact that during the first years of operation the annual pumping costs are less than one-half those under full development of the project.

Mr. Bennett suggests a more southerly diversion from the Colorado River and the joint use of the Imperial Canals. Such a route would have the lowest initial cost of any of those described for the proposed aqueduct; but with the great amount of pumping and the necessity of desilting the water by settling basins or other means, it would be the most expensive to operate and maintain.

Paper No. 1732

### THE STIFFNESS OF SUSPENSION BRIDGES\*

By S. TIMOSHENKO,† Esq.

WITH DISCUSSION BY MESSRS. LLOYD G. FROST, HANS H. RODE, E. STEUERMANN,  
GEORGE C. PRIESTER, AND S. TIMOSHENKO.

#### SYNOPSIS

In this paper a method is developed by which the additional cable stress and the deflection curve produced in a suspension bridge either by live load or by temperature variation may be directly calculated. Due to the quick convergence of the series used, the deflections and the bending moments in the span truss can be calculated in much shorter time than by the usual method.

#### I.—INTRODUCTION

The theory of the stiffened suspension bridge originated with Rankine and was developed on the assumption that the suspended truss remains absolutely rigid under the action of live load; further development was made by Professor Melan,‡ who first took into consideration the deflection of the span truss. The application of this theory to the design of large American suspension bridges, such as the Manhattan Bridge, in New York, N. Y., and the Philadelphia-Camden Bridge, showed§ that this more exact theory is of great practical importance; furthermore, it resulted in a considerable economy of material.

In applying Melan's theory to determine the additional horizontal component of the cable stress due to any cause, such as live load or temperature change, the assumption has been made that not only dead load but also additional load may be considered as uniformly distributed along the span. In

\* Published in May, 1928, *Proceedings*.

† Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

‡ This theory is discussed in detail in "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, Vol. II, p. 276.

§ *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 919.

this manner an equation has been established from which the additional cable stress can be calculated by a "cut-and-try" method. The assumption of uniform load distribution is sufficiently accurate provided the span is fully loaded, or nearly so; but a considerable error may occur when only a small part of the structure is loaded.\*

In this paper a method is developed by which (1) the actual distribution of live load can be taken into consideration; and (2) the additional cable stress produced either by such a load or by temperature variation may be directly calculated. In using this method the deflection curve of the span truss is presented in the form of a trigonometrical series, the terms of which can easily be calculated from a consideration of the energy of the system.

## II.—DIFFERENTIAL EQUATIONS FOR THE DEFLECTION CURVE OF THE SPAN TRUSS

Consider first the case shown in Fig. 1.† It is assumed that the initial curve of the cable is parabolic and that the entire dead load is carried by the cable and causes no stress in the stiffening trusses. The truss is only stressed by live load and by changes in temperature from the normal.

Let,

$H_w$  = horizontal component of cable stress, due to dead load and mean temperature.

$H$  = additional horizontal component of cable stress, due to any cause, such as live load or temperature change.

$$\beta = \frac{H}{H_w}$$

$\eta$  = deflection of truss and cable at any point, from the normal position, due to  $H$ , plus any given live load (the effect of the stretch of the hangers is neglected).

$w$  = dead load per unit length = load on cable, including its own weight.

$p$  = live load per unit length over a part or all of the span truss.

$EI$  = flexural rigidity of the span truss, assumed to be constant along the span.

$q$  = additional load on the cable, due to live load or temperature change.

$f$  = the sag of the cable.

$l$  = the span of the stiffened truss.

The differential equation of the initial curve of the cable is:

$$H_w \frac{d^2 y}{dx^2} = -w \dots \dots \dots (a)$$

By integration the known parabolic deflection curve is:

$$y = \frac{4fx(l-x)}{l^2} \dots \dots \dots (1)$$

\* "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, Vol. II, p. 312.

† The notations and initial assumptions are the same as those contained in "The Theory and Practice of Modern Framed Structures."

When an additional vertical load,  $q$ , is acting on the cable, the differential equation of the curve of the cable becomes:

$$(H_w + H) \frac{d^2}{dx^2} (y + \eta) = - (w + q) \dots \dots \dots (b)$$

From Equations (a) and (b) the load,  $q$ , transmitted to the cable will be obtained:

$$q = -H \frac{d^2}{dx^2} (y + \eta) - H_w \frac{d^2 \eta}{dx^2}$$

or,

$$q = \beta w - H_w (1 + \beta) \frac{d^2 \eta}{dx^2} \dots \dots \dots (2)$$

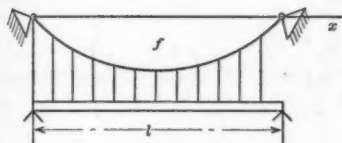

FIG. 1.

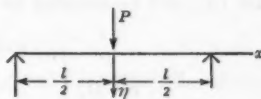

FIG. 2.

The load transmitted to the span truss will be:

$$p - q = p - \beta w + H_w (1 + \beta) \frac{d^2 \eta}{dx^2} \dots \dots \dots (3)$$

Substituting this in the known differential equation of the deflection curve of a beam of uniform cross-section, the following equation for the deflection curve of the span truss will be obtained:

$$E I \frac{d^4 \eta}{dx^4} = p - \beta w + H_w (1 + \beta) \frac{d^2 \eta}{dx^2} \dots \dots \dots (4)$$

This is a linear differential equation with constant coefficients, which can easily be solved in any particular case provided the load,  $p$ , and the change,  $H$ , of the horizontal component of the cable stress are known.

### III.—PARTICULAR CASE

Assume that a concentrated load,  $P$ , is applied at the middle of the span truss (Fig. 2), and that the change,  $H$ , in the horizontal component of the cable stress can be neglected in comparison with  $H_w$ . Then,  $p = 0$ ,  $\beta = 0$ , and Equation (4) becomes:

$$E I \frac{d^4 \eta}{dx^4} - H_w \frac{d^2 \eta}{dx^2} = 0 \dots \dots \dots (5)$$

The general solution of this equation is,

$$\eta = A e^{kx} + B e^{-kx} + Cx + D \dots \dots \dots (6)$$

in which,  $A$ ,  $B$ ,  $C$ , and  $D$  are arbitrary constants,  $e$  is the Napierian base, and,

$$k = \sqrt{\frac{H_w}{EI}} \dots \dots \dots (7)$$

The arbitrary constants must now be determined from the conditions at the ends and at the middle of the span. At the end,  $x = \frac{l}{2}$ ,

$$(\eta)_{x=\frac{l}{2}} = 0; \left(\frac{d^2 \eta}{dx^2}\right)_{x=\frac{l}{2}} = 0 \dots \dots \dots (c)$$

At the middle, the tangent must be horizontal and the shearing force equal to  $-\frac{P}{2}$ ; therefore,

$$\left(\frac{d \eta}{dx}\right)_{x=0} = 0; E I \frac{d^3 \eta}{dx^3} = \frac{P}{2} \dots \dots \dots (d)$$

It is easy to show by differentiation that Equation (5) and the conditions, (c) and (d), will be satisfied by taking,

$$\eta = \frac{P}{2 k H_w} \left( -\frac{\sinh k \left( \frac{l}{2} - x \right)}{\cosh \frac{k l}{2}} + k \left( \frac{l}{2} - x \right) \right) \dots \dots \dots (8)$$

from which,

$$\eta_{\max.} = \frac{P}{2 H_w} \left( \frac{l}{2} - \frac{1}{k} \tanh \frac{k l}{2} \right)$$

$$M_{\max.} = -E I \left( \frac{d^2 \eta}{dx^2} \right)_{x=0} = \frac{P}{2 k} \tanh \frac{k l}{2}$$

Take, for instance,\*

$$P = 100\,000 \text{ lb.};$$

$$E I = 29 \times 10^6 \times 43\,900 \times 144 \text{ lb. per sq. in.};$$

$$H_w = 10.48 \times 10^6 \text{ lb.}; \text{ and}$$

$$l = 1\,447.12 \text{ in.}$$

Then,

$$\frac{1}{k} = \sqrt{\frac{E I}{H_w}} = 349 \text{ ft.}$$

$$\eta_{\max.} = 22.0 \text{ in.}; M_{\max.} = \frac{P}{2 k} \tanh \frac{k l}{2} = 0.968 \frac{P}{2 k}$$

Comparing these results with the deflection,

$$\frac{P l^3}{48 E I} = 59.5 \text{ in.}$$

and with the maximum bending moment,

$$M_{\max.} = \frac{P l}{4} = \frac{P \times 1\,447}{4} \text{ ft.-lb.}$$

for a simply supported beam, it can be concluded that due to the support provided by the cable the deflection of the span truss is reduced to about one-third and the maximum moment to about one-half that of an unsupported truss.

For a load,  $P$ , unsymmetrically applied or a distributed load,  $p$ , covering only a part of the span, the determination of the arbitrary constants of the

\* These numerical data represent the middle span of the Manhattan Bridge.

general solution, Equation (6), becomes more complicated and a method based on the use of a trigonometrical series for the deflection curve (Section IV) is simpler for numerical calculations.

#### IV.—APPLICATION OF TRIGONOMETRICAL SERIES

The deflection curve of a beam with simply supported ends (Fig. 3) always can be represented in the form of the trigonometrical series,

$$\eta = a_1 \sin \frac{\pi x}{l} + a_2 \sin \frac{2\pi x}{l} + a_3 \sin \frac{3\pi x}{l} + \dots \quad (9)$$

in which  $a_1, a_2, a_3, \dots$ , are coefficients which can be calculated from a consideration of the energy of the system.

By using for the potential energy of bending according to the well-known equation,

$$U = \frac{EI}{2} \int_0^l \left( \frac{d^2 \eta}{dx^2} \right)^2 dx$$

substituting from Equation (9) for  $\eta$ ; and taking into consideration that,

$$\int_0^l \sin \frac{m\pi x}{l} \sin \frac{n\pi x}{l} dx = 0$$

and,

$$\int_0^l \sin^2 \frac{m\pi x}{l} dx = \frac{l}{2}$$

the potential energy becomes,

$$U = \frac{EI\pi^4}{4l^3} (a_1^2 + 2^4 a_2^2 + 3^4 a_3^2 + \dots) \quad (10)$$

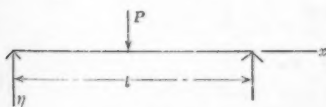

FIG. 3.

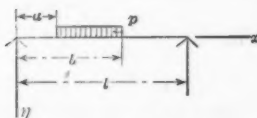

FIG. 4.

Assuming that a small increase,  $\delta a_n$ , is given to one of the coefficients,  $a_n$ , of the series in Equation (9), a small additional deflection,  $\delta a_n \sin \frac{n\pi x}{l}$ , will be superimposed on the deflection given by Equation (9); then, from the condition of equilibrium it can be concluded that the work done by loads acting on the beam during the displacement,  $\delta a_n \sin \frac{n\pi x}{l}$ , must be equal to the increase of the potential energy, Equation (10). In the case already considered the beam was under the action of a load,  $P$ , applied at the middle, and of a distributed load,  $H_w \frac{d^2 \eta}{dx^2}$  (see Equation (5)), representing the action of the cable on the beam. The work done during the small displacement,  $\delta a_n \frac{\sin n\pi x}{l}$ , by the load,  $P$ , will be,

$$P \delta a_n \sin \frac{n\pi}{2} \dots \dots \dots (e)$$

The work done by the distributed load,  $H_w \frac{d^2 \eta}{dx^2}$ , will be,

$$\int_0^l H_w \frac{d^2 \eta}{dx^2} \delta a_n \sin \frac{n \pi x}{l} dx$$

or, substituting for  $\eta$  from Equation (9), and considering that only the term containing the coefficient,  $a_n$ , gives an integral different from zero, the expression for this work becomes,

$$- H_w \delta a_n a_n \frac{n^2 \pi^2}{2 l} \dots \dots \dots (f)$$

The increase of the potential energy,  $U$ , Equation (10), due to the small displacement,  $a_n \sin \frac{n \pi x}{l}$ , will be :

$$\frac{\delta U_n}{\delta a_n} \delta a_n = \frac{E I \pi^4 n^4}{2 l^3} a_n \delta a_n \dots \dots \dots (g)$$

Equating Equation (g) to the sum of Equations (f) and (e),

$$\frac{E I \pi^4 n^4}{2 l^3} a_n = - H_w a_n \frac{n^2 \pi^2}{2 l} + P \sin \frac{n \pi}{2}$$

from which, when  $n$  is odd,

$$a_n = \frac{2 P l^3}{E I \pi^4} \frac{\sin \frac{n \pi}{2}}{n^4 + n^2 \alpha} \left. \dots \dots \dots (h) \right\}$$

and, when  $n$  is even,

$$a_n = 0$$

in which,

$$\alpha = \frac{H_w l^2}{E I \pi^2} \dots \dots \dots (11)$$

Substituting Equation (h) in Equation (9),

$$\eta = \frac{2 P l^3}{E I \pi^4} \left( \frac{\sin \frac{\pi x}{l}}{1 + \alpha} - \frac{\sin \frac{3 \pi x}{l}}{3^4 + 3^2 \alpha} + \frac{\sin \frac{5 \pi x}{l}}{5^4 + 5^2 \alpha} \dots \right)$$

The deflection at the middle  $\left(x = \frac{l}{2}\right)$  will be,

$$\eta_{\max.} = \frac{2 P l^3}{E I \pi^4} \left( \frac{1}{1 + \alpha} + \frac{1}{81 + 9 \alpha} + \frac{1}{625 + 25 \alpha} + \dots \right)$$

The series is quickly convergent and very convenient for numerical calculations.

Applying this to the previous numerical example,

$$\alpha = \frac{H_w l^2}{E I \pi^2} = 1.75$$

\*The term,  $\alpha$ , has a very simple meaning. It represents the ratio of the horizontal component,  $H_w$ , of the cable stress to the column load of the span truss.

and,

$$\eta_{\max} = \frac{2 P l^3}{E I \pi^4} \left( \frac{1}{2.75} + \frac{1}{96.9} + \frac{1}{668.7} + \dots \right) = 0.376 \frac{2 P l^3}{E I \pi^4} = 22.0 \text{ in.}$$

Within the accuracy of the slide-rule this result coincides with the former solution.

This method can also be applied to the general case given by the differential Equation (4), in which the load acting on the truss is given by Equation (3). Taking, again, the series of Equation (9) for the deflection curve and assuming that the live load,  $p$ , is uniformly distributed between the limits,  $x = a$  and  $x = b$ , as shown in Fig. 4, the work done by the live load

on a small displacement,  $\delta a_n \sin \frac{n \pi x}{l}$ , will be,

$$p \delta a_n \int_a^b \sin \frac{n \pi x}{l} dx = \delta a_n \frac{p l}{n \pi} \left( \cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l} \right)$$

The work done by the reactions from the cable on the truss will be,

$$\begin{aligned} -\delta a_n \beta w \int_0^l \sin \frac{n \pi x}{l} dx + \delta a_n H_w (1 + \beta) \int_0^l \frac{d^2 \eta}{dx^2} \sin \frac{n \pi x}{l} dx \\ = -\delta a_n \frac{l}{n \pi} \beta w (1 - \cos n \pi) - a_n \delta a_n H_w (1 + \beta) \frac{n^2 \pi^2}{2 l} \end{aligned}$$

The equation for determining  $a_n$  becomes,

$$\begin{aligned} \frac{p l}{n \pi} \left( \cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l} \right) - \frac{l}{n \pi} \beta w (1 - \cos n \pi) \\ - a_n H_w (1 + \beta) \frac{n^2 \pi^2}{2 l} = \frac{n^4 E I \pi^4}{2 l^3} a_n \end{aligned}$$

from which,

$$a_n = \frac{\frac{p l}{n \pi} \left( \cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l} \right) - \frac{l}{n \pi} \beta w (1 - \cos n \pi)}{\frac{n^4 E I \pi^4}{2 l^3} + H_w (1 + \beta) \frac{n^2 \pi^2}{2 l}}$$

or, when  $n$  is odd,

$$a_n = \frac{2 l^4}{E I \pi^5 (n^5 + n^3 \alpha (1 + \beta))} \left( p \left( \cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l} \right) - 2 \beta w \right) \quad \left. \begin{aligned} \text{and, when } n \text{ is even,} \\ a_n = \frac{2 p l^4}{E I \pi^5 (n^5 + n^3 \alpha (1 + \beta))} \left( \cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l} \right) \end{aligned} \right\} \cdot (12)$$

Substituting from Equations (12) in Equation (9), a quickly convergent series will be obtained from which the deflections can be calculated for any distribution of live load, provided that the additional horizontal component,  $H$ , of the cable stress is known.

Assuming, for instance, that the live load covers only one-quarter of the span to the left support of the truss, and substituting  $a = 0$  and  $b = \frac{l}{4}$  in

Equations (12), the deflection curve is obtained in the form of the following series:

$$\eta = \frac{2 l^4}{E I \pi^5} \left( \frac{p \left( 1 - \cos \frac{\pi}{4} \right) - 2 \beta w}{1 + \alpha (1 + \beta)} \sin \frac{\pi x}{l} + \frac{p \sin \frac{2 \pi x}{l}}{2^5 + 2^3 \alpha (1 + \beta)} \right. \\ \left. + \frac{p \left( 1 - \cos \frac{3 \pi}{4} \right) - 2 \beta w}{3^5 + 3^3 \alpha (1 + \beta)} \sin \frac{3 \pi x}{l} + \dots \right) \dots \dots (13)$$

from which, the deflection can be calculated if  $\beta = \frac{H}{H_w}$  is known.

For calculating the bending moments the second derivative of Equation (13) must be calculated and substituted in the known equation,  $M = -E I \frac{d^2 \eta}{dx^2}$ .

If there is no live load and if the effects of temperature alone on the deflection are being considered, then from Equations (12), when  $n$  is odd,

$$a_n = - \frac{4 \beta w l^4}{E I \pi^5 (n^5 + n^3 \alpha (1 + \beta))}$$

and, when  $n$  is even,

$$a_n = 0$$

The deflection curve will then be,

$$\eta = - \frac{4 \beta w l^4}{E I \pi^5} \left( \frac{\sin \frac{\pi x}{l}}{1 + \alpha (1 + \beta)} + \frac{\sin \frac{3 \pi x}{l}}{3^5 + 3^3 \alpha (1 + \beta)} \right. \\ \left. + \frac{\sin \frac{5 \pi x}{l}}{5^5 + 5^3 \alpha (1 + \beta)} + \dots \right) \dots \dots (14)$$

The minus sign indicates that an increase in cable stress, ( $\beta > 0$ ), produces a deflection of the truss in an upward direction.

#### V.—DETERMINATION OF THE ADDITIONAL HORIZONTAL COMPONENT OF CABLE STRESS

To determine  $H$ , the additional cable stress due to live load or to change in temperature, the change in potential energy of the cable must be calculated. The initial tensile force in the cable for any section is,

$$H_w \frac{ds}{dx}$$

and the potential energy of tension in an element,  $ds$ , will be,

$$\frac{\left( H_w \frac{ds}{dx} \right)^2}{2 A E} ds$$

in which,  $A$  is the area of the cross-section of the cable.

The increase of this energy, due to an additional horizontal component,  $H$ , will be,

$$\frac{(H_w + H)^2 \left(\frac{ds}{dx}\right)^2 ds}{2AE} - \frac{H_w^2 \left(\frac{ds}{dx}\right)^2 ds}{2AE} = \frac{H \left(H_w + \frac{1}{2}H\right) ds^3}{AE dx^2}$$

so that the complete change in the energy of the cable will be:

$$\frac{H \left(H_w + \frac{1}{2}H\right)}{AE} \int_0^L \frac{ds^3}{dx^2} = \frac{H \left(H_w + \frac{1}{2}H\right)}{AE} L \dots \dots (15)$$

in which,

$$L = \int_0^L \frac{ds^3}{dx^2}$$

Taking as the basis of calculation the parabolic curve given by Equation (1),

$$L = l \left[ \frac{1}{4} \left( \frac{5}{2} + \frac{16f^2}{l^2} \right) \left( 1 + \frac{16f^2}{l^2} \right)^{\frac{1}{2}} + \frac{3}{32} \log_e \left( \frac{4f}{l} + \left( 1 + \frac{16f^2}{l^2} \right)^{\frac{1}{2}} \right) \right] \dots \dots (16)$$

The increase in energy, Equation (15), must be equal to the work done by the load acting on the cable. The intensity of the initial load is  $w$ . The intensity of the final load is (Equation (2)),

$$w + q = w + \beta w - H_w (1 + \beta) \frac{d^2 \eta}{dx^2}$$

Assuming that, for small variations in cable stress, the deflections are proportional to the load, an average value of the intensity of the load must be taken when calculating the work done. Hence,

$$T = \int_0^L \left( w + \frac{q}{2} \right) \eta dx = \int_0^L \left( w + \frac{w\beta}{2} - \frac{H_w}{2} (1 + \beta) \frac{d^2 \eta}{dx^2} \right) \eta dx$$

Substituting from Equation (9) for  $\eta$ ,

$$T = \left( w + \frac{w\beta}{2} \right) \frac{2l}{\pi} \left( a_1 + \frac{a_3}{3} + \frac{a_5}{5} + \dots \right) + \pi^2 \frac{H_w}{4l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots \dots (17)$$

Equating this to the increase in potential energy of the cable,

$$\frac{H_w^2 \beta \left( 1 + \frac{1}{2} \beta \right)}{AE} L = \left( w + \frac{w\beta}{2} \right) \frac{2l}{\pi} \left( a_1 + \frac{a_3}{3} + \frac{a_5}{5} + \dots \right) + \pi^2 \frac{H_w}{4l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots)$$

or,

$$\frac{H_w L}{A E} \beta \left(1 + \frac{1}{2} \beta\right) = \frac{16 f}{\pi l} \left(1 + \frac{\beta}{2}\right) \left(a_1 + \frac{a_3}{3} + \frac{a_5}{5} + \dots\right) + \frac{\pi^2}{4 l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots\dots\dots (18)$$

The coefficients,  $a_1, a_2, a_3, \dots$ , can be calculated in each particular case as already explained (Section IV), so that Equation (18) establishes a definite relation between  $\beta$  and the live load,  $p$ . The simplest way to solve this equation for any particular load distribution is to assume a certain value for  $\beta$ , that is, a certain increase in horizontal component of cable stress and to calculate, from Equation (18), the intensity of the live load,  $p$ , necessary to produce such an increase in cable stress. Then assuming, for small fluctuation in cable stress, that  $\beta$  is proportional to  $p$ , the additional cable stress for any value of  $p$  can easily be calculated.

In order to show the procedure take the numerical example already considered, and assume that,  $f = 145.3$  ft.;  $A = 275$  in. square = area of cross-section of cable; and  $w = 5820$  lb. per lin. ft. = intensity of dead load. Then, using the previous data,

$$\alpha = \frac{H_w l^2}{E I \pi^2} = 1.75$$

and,

$$L = \int_0^l \frac{d s^3}{d x^2} = 1564 \text{ ft.}$$

Consider the case where the live load covers only one-quarter of the span to the left support of the truss and the deflection curve is represented by Equation (13). Assume that the intensity,  $p$ , of the live load is such that a definite increase in cable stress is produced. Take, for instance,

$$\beta = \frac{H}{H_w} = 0.2$$

Then the series, Equation (13), becomes,

$$\eta = \frac{2 l^4}{E I \pi^5} \left( \frac{0.2929 p - 0.4 w}{1 + 1.75 \times 1.2} \sin \frac{\pi x}{l} + \frac{p \sin \frac{2 \pi x}{l}}{2^5 + 2^3 \times 1.75 \times 1.2} + \frac{1.7071 p - 0.4 w}{3^5 + 3^3 \times 1.75 \times 1.2} \sin \frac{3 \pi x}{l} + \frac{2 p \sin \frac{4 \pi x}{l}}{4^5 + 4^3 \times 1.75 \times 1.2} + \frac{1.7071 p - 0.4 w}{5^5 + 5^3 \times 1.75 \times 1.2} \sin \frac{5 \pi x}{l} + \dots \right) \dots\dots\dots (19)$$

and, hence,

$$a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots = \frac{2 l^4}{E I \pi^5} (0.0965 p - 62.81)$$

and,

$$a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots = \left( \frac{2 l^4}{E I \pi^5} \right)^2 (0.01096 p^2 - 11.89 p + 3920)$$

Substituting these values in Equation (18), the following quadratic equation for determining  $p$ , will be obtained,

$$5.45 = 1.827(0.0965 p - 62.81) + 0.001797(0.01096 p^2 - 11.89 p + 3\,920)$$

or,

$$0.0000197 p^2 + 0.1555 p - 113.4 = 0$$

from which,

$$p = 671 \text{ lb. per lin. in.}$$

This is the intensity of the live load necessary to produce an increase,  $H$ , in the horizontal component equal to  $0.2 H_w$ . The increase in cable stress for any other intensity of live load can easily be calculated. Assume, for instance, that a live load of 4 000 lb. per lin. ft. covers the truss between the limits,  $x = 0$  and  $x = \frac{l}{4}$ ; then the corresponding increase in the horizontal component of the cable stress will be,

$$H = \frac{0.2 H_w \times 4\,000}{12 \times 671} = 1\,040\,000 \text{ lb.}$$

In these calculations it has been assumed that  $\beta$  varies in the same proportion as the load,  $p$ ; but as can be seen from the fundamental Equation (18), this assumption is not strictly correct. In order to show what errors may be involved in such an assumption additional calculations were made for the load covering only one-quarter of the span to the left support of the truss and in two different ways.\* In the first case, after calculating  $p$  for  $\beta = 0.05$ , in the same manner as before, the values of  $p$  for other values of  $\beta$  were found on the assumption that there is a simple proportionality between  $\beta$  and  $p$ . In this manner the figures in the second line of the following tabulation were obtained. In the second case, the loads,  $p'$ , were calculated from Equation (18) independently for each value of  $\beta$ .

Value of $\beta$	=	0.05	0.1	0.2	0.4
Value of $p$	=	169.4	338.8	677.6	1 355
Value of $p'$	=	169.4	338.5	673.0	1 322

It is seen from this tabulation that there is a slight deviation from the proportionality between  $\beta$  and  $p$ , namely,  $\beta$  is increasing somewhat more rapidly than  $p$ . This means that with the increase in load,  $p$ , a large proportional part of the load will be taken by the cable. At the same time this deviation from proportionality is small and a conclusion can be made that in calculating  $p$  from Equation (18) a rough approximation for  $\beta$  will be sufficient for obtaining  $p$  with a satisfactory accuracy.

In the deviation of the general expression for the work done by the load acting on the cable (see Equation (17)), the average value,  $w + \frac{q}{2}$ , for the load was used. This is strictly correct only when the deflections are proportional to the loads. To find what errors are involved in this method of calculation

\* These calculations were made by Professor G. C. Priester. A more accurate value for  $\alpha$ , namely, 174.6, was taken in this case and all calculations were made to four significant figures.

tion an additional investigation was made by dividing the process of loading into two steps, each step representing the loading by a load of one-half the final intensity. In calculating the cable stress for the first step, the previous method was used. For the second step the calculations of the cable stress were made by taking into account the changes in the cable stress and in the loads produced by the loadings of the first step. These calculations showed that the errors involved in this method of determining the work done by the loads acting on the cable are very small for the usual values of  $\beta$  and can be neglected.

In addition, it is interesting to note that the second term on the right side of Equation (18), representing the influence of deflection of the truss on the distribution of the load transmitted to the cable, is usually small. This fact explains why the ordinary theory of suspension bridges, which assumes that the load acting on the cable is uniformly distributed, yields satisfactory results.

#### VI.—THE CASE OF THREE SPANS

The method just developed can be applied in the case of three spans, such as shown in Fig. 5. Assuming that the cable can move without friction at the top of the towers, the horizontal component of the cable stress will be constant along all three spans. For calculating the deflections of the middle span the equations already derived can be used.

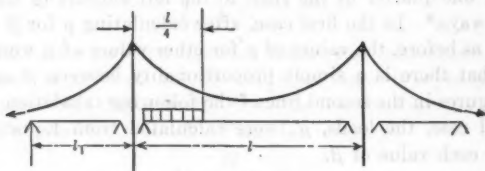

FIG. 5.

In considering the side spans let,

$l_1$  = length of side span;

$w_1$  = dead load of side span; and

$E I_1$  = flexural rigidity of side-span truss.

Taking the deflection curve of the side-span truss in the form of the series:

$$\eta_1 = b_1 \sin \frac{\pi x}{l_1} + b_2 \sin \frac{2 \pi x}{l_1} + b_3 \sin \frac{3 \pi x}{l_1} + \dots \quad (9a)$$

in which,  $x$  is measured from the left end of the span. The coefficients,  $b_1, b_2, \dots$ , can be calculated by using equations similar to Equations (12). Assuming, for instance, that there is no live load on the side spans (Fig. 5), Equation (14) becomes

$$\eta_1 = - \frac{4 \beta w_1 l_1^4}{E I_1 \pi^6} \left( \frac{\sin \frac{\pi x}{l_1}}{1 + \alpha_1 (1 + \beta)} + \frac{\sin \frac{3 \pi x}{l_1}}{3^5 + 3^3 \alpha_1 (1 + \beta)} + \dots \right) \quad (14a)$$

in which,

$$\alpha_1 = \frac{H_w l_1^2}{E I_1 \pi^2}$$

For calculating the additional horizontal component,  $H$ , of the cable stress an equation analogous to Equation (18) can be derived. For this purpose, it is only necessary to put the complete length of the cable for  $L$  on the left side of Equation (18) and add to the right side the work done by loads acting on the side parts of the cable. This latter work will be:

$$T_1 = 2 \int_0^{l_1} \left( w_1 + \frac{w_1 \beta}{2} - \frac{H_w}{2} (1 + \beta) \frac{d^2 \eta_1}{dx^2} \right) \eta_1 dx$$

Substituting the series, Equation (9a), for  $\eta_1$ ,

$$T_1 = 2 \left( w_1 + \frac{w_1 \beta}{2} \right) \frac{2 l_1}{\pi} \left( b_1 + \frac{1}{3} b_3 + \frac{1}{5} b_5 + \dots \right) + \frac{\pi^2 H_w}{2 l_1} (1 + \beta) (b_1^2 + 2^2 b_2^2 + 3^2 b_3^2 + \dots) \dots \dots (20)$$

The equation for determining  $H$  will be,

$$\frac{H_w^2 L}{A E} \beta \left( 1 + \frac{1}{2} \beta \right) = \left( w_1 + \frac{w_1 \beta}{2} \right) \frac{4 l_1}{\pi} \left( b_1 + \frac{1}{3} b_3 + \frac{1}{5} b_5 \right) + \frac{\pi^2 H_w}{2 l_1} (1 + \beta) (b_1^2 + 2^2 b_2^2 + 3^2 b_3^2 + \dots) + \left( w + \frac{w \beta}{2} \right) \frac{2 l}{\pi} \left( a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots \right) + \frac{\pi^2 H_w}{4 l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots (21)$$

For the numerical example already considered assume that,

$$l_1 = 713.5 \text{ ft.}$$

$$w_1 = 6130 \text{ lb. per lin. ft.}$$

$$E I_1 = 29 \times 10^6 \times 50860 \times 144 \text{ lb. per sq. in.; and}$$

$$L = 3452 \text{ ft.}$$

Then, assuming the loading shown in Fig. 5, the deflection curve of the middle span truss will be given by Equation (19) as before. The deflection curves for the side span trusses will be represented by Equation (14a), so that, substituting the numerical values, and taking  $\beta = 0.2$ ,

$$\alpha_1 = \frac{H_w l_1^2}{E I_1 \pi^2} = 0.3664$$

and,

$$\eta_1 = -23.46 \sin \frac{\pi x}{l} - 0.132 \sin \frac{3 \pi x}{l} + \dots$$

then,

$$b_1 + \frac{1}{3} b_3 + \dots = -23.5 \text{ in.; } b_1^2 + 3^2 b_3^2 + \dots = 552 \text{ in. square.}$$

Substituting in Equation (21),

$$11.97 = 1.827 (0.0965 p - 62.81) + 0.001797 (0.01096 p^2 - 11.89 p + 3920) - 13.8 + 0.38$$

or,

$$0.0000197 p^2 + 0.1555 p - 133.3 = 0$$

from which,

$$p = 780 \text{ lb. per lin. in.}$$

If a load of the intensity of 4 000 lb. per ft. is acting on the part of the middle span shown in Fig. 5, the increase in the horizontal component will be,

$$H = \frac{0.2 H_w \times 4\,000}{12 \times 780} = 897\,000 \text{ lb. } \pm$$

#### VII.—EFFECT OF CHANGE IN TEMPERATURE

The same method can also be used in calculating the additional horizontal component,  $H$ , of the cable stress produced by a change in temperature. Let,

$$\omega = 66 \times 10^{-7} = \text{coefficient of linear expansion per degree Fahrenheit; and}$$

$$L_t = \int_0^l \frac{ds}{dx} dx$$

Then, the work in the cable due to temperature is:\*

$$\int_0^l \left( H_w + \frac{H}{2} \right) \frac{ds}{dx} \omega t ds = H_w \left( 1 + \frac{\beta}{2} \right) \omega t L_t$$

Using for the change in potential energy of the cable, Equation (10), as before, the total work in the cable becomes,

$$\frac{H_w^2 \beta \left( 1 + \frac{\beta}{2} \right)}{A E} L + H_w \left( 1 + \frac{\beta}{2} \right) \omega t L_t$$

This work must be equal to that done by the vertical load acting on the cable. For this later work Equations (17) and (20) will be used. The equation for determining  $H$  will be,

$$\begin{aligned} & \frac{H_w^2 \beta \left( 1 + \frac{\beta}{2} \right)}{A E} L + H_w \left( 1 + \frac{\beta}{2} \right) \omega t L_t = \left( w + \frac{w \beta}{2} \right) \frac{2 l}{\pi} \\ & \left( a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots \right) + \frac{\pi^2 H_w}{4 l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \\ & + \left( w_1 + w_1 \frac{\beta}{2} \right) \frac{2 l_1}{\pi} \left( b_1 + \frac{1}{3} b_3 + \frac{1}{5} b_5 + \dots \right) \\ & + \frac{\pi^2 H_w}{4 l_1} (1 + \beta) (b_1^2 + 2^2 b_2^2 + 3^2 b_3^2 + \dots) \dots \dots \dots (22) \end{aligned}$$

Applying these equations, as before, to a bridge with three spans and assuming that  $\beta = 0.2$  and  $L_t = \int \frac{ds^2}{dx} = 3\,324 \text{ ft.}$ , and letting  $p = 0$ ,

$$11.97 + 1.1 \omega t \times 3\,324.12 = -1.827 \times 62.81 + 0.001979 \times 3\,920 \\ - 13.8 + 0.38$$

\* It is assumed that the fluctuations in the cable stress are small; and the average stress,  $H_w + \frac{H}{2}$ , is taken in calculations.

or,

$$1.1 \times 3\,824 \times 12 \times \omega t = -133.3$$

from which,

$$\omega t = -0.00304$$

Assuming that  $\omega = 66 \times 10^{-7}$  in. per in. per degree Fahrenheit,

$$t = -461^\circ \text{ Fahr.}$$

Now the additional horizontal component,  $H$ , for any variation in temperature can easily be calculated. Assuming, for instance, that the temperature increased  $55^\circ$  Fahr. above normal,

$$H = -\frac{H_w \times 0.2 \times 55}{461} = -250\,000 \text{ lb.}$$

Combining this effect of the increase in temperature with that already calculated, due to the load distributed as shown in Fig. 5, the complete change in the horizontal component of cable stress will be,

$$H = 897\,000 - 250\,000 = 647\,000 \text{ lb.}$$

which differs only about 2½% from the result given by Messrs. Johnson, Bryan, and Turneaure.\* This agreement seems satisfactory considering that all the calculations were made with a slide-rule and that an approximate value for the coefficient of thermal expansion was used. A better approximation will be obtained by using the given value of  $EI$  as a first trial and by calculating a more accurate value of  $\beta$  from Equation (22).

#### CONCLUSIONS

It has been shown that by using a trigonometric series for the deflection curve of the span truss a direct calculation of the change in the horizontal component of the cable stress becomes possible; and that the actual distribution of the live load can easily be taken into account in this calculation. Due to the quick convergence of the series representing the deflection curves, the calculation of the deflections and of the bending moments in the span truss can be made without difficulty and in a much shorter time than by the usual method.

## DISCUSSION

LOYD G. FROST,\* ASSOC. M. AM. SOC. C. E. (by letter).—The method developed by the author should serve to advantage as a check on the established procedure; its mathematical concept is clear and ably expounded. The title, however, is misleading, giving as it does the impression that the subject matter deals with the stiffening system from the standpoint of comparative design, whereas it is found to be a purely mathematical treatise in which a method is developed by which calculations can be made in a "much shorter time than by the usual method."

This description suggests the possibility of applying this method to the preparation of cost estimates. In this connection the writer has had occasion to prepare complete and exhaustive estimates and investigations of the cost of a proposed suspension bridge over the Mississippi River at New Orleans, La. These investigations were extended to comparisons of fixed and rocker towers, eye-bar and wire cables, also the combination of the cables with a part of the top chord of the stiffening truss, and the variation of the depth of the stiffening truss after the method used by D. B. Steinman and William G. Grove, Members, Am. Soc. C. E., in the design of the Florianopolis Bridge,† was reviewed as well.

Estimates were first based on the elastic theory and then revised by the deflection method. Finally, the results obtained were compared with estimates prepared from the data and curves presented by J. A. L. Waddell, M. Am. Soc. C. E.‡ The agreement was within 3%, which amounts to a practical check.

The considerable labor involved in determining a satisfactory basis of estimate amounted virtually to a complete design as regards fundamentals, and the results finally obtained indicate that for all practical purposes of preliminary estimates, curves such as those prepared by Mr. Waddell are sufficiently accurate. It is well known that very few engineers are called upon to design suspension bridges; and then, in many cases, such work goes no further than preliminary estimates of cost.

Most engineers are inclined to view with a certain skepticism any mathematical "short-cuts" with which they are unfamiliar; and, if used, to check them thoroughly with methods they are accustomed to employ. The paper under discussion presupposes a facility with the calculus which, in the writer's opinion, a majority of able and practical designers do not have. The method developed in this paper is to some extent shorter than that ordinarily used in calculations of this nature; but the practical value of such shortening seems somewhat doubtful.

On the rare occasions that the engineer is called upon to design suspension bridgework, his first and in all probability his only necessity for quick methods of calculation will have to do with the preparation of preliminary estimates of cost. Once the work is in the hands of the designers for final

† *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 266.

‡ *Loc. cit.*, Vol. 91 (1927), p. 884.

development, the matter of time involved in design calculation becomes of small moment; and the calculation of bending moments and deflections in the truss constitutes a very small part of the work involved.

While perhaps of interest to the engineer who has a flair for abstract mathematical analysis, the writer believes this paper to be largely another leaf in the already imponderable tome of matter that serves but a small minority and is of little value to the busy engineer in the practice of his profession.

HANS H. RODE,\* M. Am. Soc. C. E. (by letter).—This paper, presented by an eminent authority in the field of applied mathematics, shows that trigonometric series can be utilized to good advantage in computations pertaining to suspension bridges. It is to be hoped that in the future such series will be as well known and as frequently used by civil engineers as they are now by the mechanical and electrical engineers.

The writer, however, cannot agree with the more specific procedure recommended in this paper. The author assumes that the additional horizontal component,  $H$ , from the live load,  $p$ , may be neglected in comparison with the horizontal component,  $H_w$ , from the dead load,  $w$ , and, on this basis, he finds a maximum deflection,  $\eta_{\max.} = 22$  in., for a concentrated load of  $P = 100\,000$  lb. at the middle of the main span of the Manhattan Bridge.

This is correct enough according to the author's method, which amounts to assuming the cables carried over sheaves and counterweighted so as to maintain a constant stress in them, but it does not represent actual conditions in suspension bridges. If the assumption were correct, large bridges would deflect 30 or 40 ft., or more, and their stiffening trusses would break. Using the author's numerical data, the correct value of  $\eta_{\max.}$  is found to be approximately 2 in.

In computing  $\eta_{\max.}$  the author has entirely ignored the condition that the horizontal projection of the cable must equal the distance between anchorages. Without this condition, in some form or other, the deflections and stresses cannot be determined.

The deductions in this paper are also based on Equation (4) which is frequently encountered in books and discussions and seems to be universally accepted as correct—which it is not.

The writer has found that the exact differential equation is rather complicated, but that it assumes a simple form if the cable strain—that is, the elongation of the cable under live load stress or from temperature, is neglected. In that case, and assuming a parabolic cable curve, the equation will be:

$$EI \frac{d^4 \eta}{dx^4} = p - \beta w + H_w (1 + \beta) \frac{d}{dx} \left( \frac{d\eta}{dx} \sec^2 \phi \right) = p - \beta w + H_w (1 + \beta) \left[ \frac{d^2 \eta}{dx^2} + \frac{d^2 \eta}{dx^2} t g^2 \phi - \frac{d}{dx} \frac{16f}{l^2} t g \phi \right] \dots \dots (23)$$

in which,  $\phi$  = the slope angle of the cable curve at any point, and,

$$\sec^2 \phi = 1 + t g^2 \phi = a + b x + c x^2$$

Equations (4) and (23) differ only in the last term on the right-hand side.

\* Prof., Norges Tekniske Høiskole, Trondhjem, Norway.

Ordinarily, Equation (4) constitutes a good approximation. This is particularly true for cables with a small sag ratio, although the effect depends largely also on the type of loading. It should be borne in mind, however, that the errors resulting from the use of Equation (4) are, in some cases, not altogether negligible.

E. STEUERMANN,\* ESQ. (by letter).—The solution of the problem presented by Professor Timoshenko is of universal significance and can be applied not only when the moment of inertia of the stiffening truss is constant within the entire span, but also when it is variable.

The author's Equation (4) may also be written in the form:

$$E I \frac{d^2 \eta}{dx^2} - H_w (1 + \beta) \eta = -M_x + \beta H_w y \dots \dots \dots (24)$$

in which,  $M_x$  is the bending moment due to the action of the external load on the truss. This formula is equally effective when the value of  $I$  is variable.

Suppose, for example, that  $I_1$ , the moment of inertia of the truss at the ends, is less than  $I_0$ , the moment of inertia at the center. This is quite a rational assumption if the truss is not continuous through the towers. The value of  $I$  may be found by the equation:

$$I = I_0 \sin \left( \frac{m \pi x}{l} + \alpha \right) \dots \dots \dots (25)$$

in which,  $\alpha = \sin^{-1} \left( \frac{I_1}{I_0} \right)$  and  $m = 1 - \frac{2\alpha}{\pi}$ . When  $I_1 = \frac{I_0}{2}$ , then  $\alpha = \frac{\pi}{6}$  and  $m = \frac{2}{3}$ .

Equation (25) imposes a definite and, in many cases, an admissible restriction on the manner in which the moment of inertia,  $I$ , shall vary, but is considered only for a specific case. The method of calculation that follows is equally applicable for the general case:

$$I = I_0 f(x) \dots \dots \dots (26)$$

Expanding the right side of Equation (24) into the series of Fourier:

$$-M_x + \beta H_w y = - \left( b_1 \sin \frac{\pi x}{l} + b_2 \sin \frac{2\pi x}{l} + \dots + b_n \sin \frac{n\pi x}{l} \right) \dots \dots \dots (27)$$

in which,

$$b_n = \frac{2}{l} \int_0^l (M_x - \beta H_w y) dx \dots \dots \dots (28)$$

The integral,  $\eta$ , may be presented in the form of a series, as follows:

$$\eta = a_1 \sin \frac{\pi x}{l} + a_2 \sin \frac{2\pi x}{l} + \dots + a_n \sin \frac{n\pi x}{l} + \dots = \sum_1^n a_n \sin \frac{n\pi x}{l} \dots \dots \dots (29)$$

Substituting in Equation (24), the values found by Equations (27) and (29), and changing signs:

$$\begin{aligned} \frac{\pi^2 E I_0}{l^2} \sin \left( \frac{m \pi x}{l} + \alpha \right) \sum_1^\infty n^2 a_n \sin \frac{n \pi x}{l} + H_w (1 + \beta) \sum_1^\infty a_n \sin \frac{n \pi x}{l} \\ = \sum_1^\infty b_n \sin \frac{n \pi x}{l} \dots \dots \dots (30) \end{aligned}$$

\* Prof., Kief Polytechnic High School, Kief, Union of Socialistic Soviet Republics.

To determine the coefficients,  $a_n$ , multiply both sides of Equation (30) by  $\sin \frac{\kappa \pi x}{l}$  (in which,  $\kappa = 1, 2, 3 \dots n$ ), and integrate between the limits 0 and  $l$ , then,

$$\frac{\pi^2 E I_0}{l^2} \sum_1^\infty n^2 a_n \int_0^l \sin \left( \frac{m \pi x}{l} + \alpha \right) \sin \frac{m \pi x}{l} \sin \frac{\kappa \pi x}{l} dx + H_w (1 + \beta) \sum_1^\infty a_n \int_0^l \sin \frac{n \pi x}{l} \sin \frac{\kappa \pi x}{l} dx = \sum_1^\infty b_n \int_0^l \sin \frac{n \pi x}{l} \sin \frac{\kappa \pi x}{l} dx. \quad (31)$$

By the known formulas of integral calculus:

$$\int_0^l \sin \left( \frac{m \pi x}{l} + \alpha \right) \sin \frac{n \pi x}{l} \sin \frac{\kappa \pi x}{l} dx = \frac{2 [(-1)^{n+\kappa+1} - 1] m l n \kappa}{\pi [(n-\kappa)^2 - m^2] [(n+\kappa)^2 - m^2]}. \quad (32)$$

Substituting Equation (32) in Equation (31) and transposing the terms:

$$a_\kappa + \frac{4 \pi E I_0 m \cos \alpha}{H_w l^2 (1 + \beta)} \sum_1^\infty \frac{[(-1)^{n+\kappa+1} - 1] \kappa n^3 a_n}{[(n-\kappa)^2 - m^2] [(n+\kappa)^2 - m^2]} = \frac{b_\kappa}{H_w (1 + \beta)}. \quad (33)^*$$

in which,  $\kappa = 1, 2, 3, \dots n$ . Let,

$$\mu = \frac{4 \pi E I_0 m \cos \alpha}{H_w l^2 (1 + \beta)} \dots \dots \dots (34)$$

$$N_{\kappa n} = \frac{[(-1)^{n+\kappa+1} - 1] \kappa n^3}{[(n+\kappa)^2 - m^2] [(n-\kappa)^2 - m^2]} \dots \dots \dots (35)$$

and,

$$C_\kappa = \frac{b_\kappa}{H_w (1 + \beta)} \dots \dots \dots (36)$$

Then, Equation (33) becomes:

$$a_\kappa + \mu \sum_1^\infty N_{\kappa n} a_n = C_\kappa \dots \dots \dots (37)$$

If Equation (29) is restricted to a definite number of terms, that is,  $\gamma$ -terms, or enough to express the value of  $\eta$  accurately, Equation (37) will also include the same definite number of terms, such that  $\kappa = 1, 2, 3, \dots \gamma$ .

Solving Equation (37) within these definite limits will express  $a_1, a_2, a_3 \dots a_\gamma$ , as well as  $\eta$  as functions of  $\beta$ . The author derives Equation (18) for use in determining the value of  $\beta$  and the same equation can be used in the present case. The remainder of the solution follows exactly the method described by the author for trusses of constant section.

The solution of Equation (37) is simplified due to the fact that it may be separated into two independent parts, one containing the term,  $a_\kappa$ , for even values of  $\kappa$  and the other, for odd values of  $\kappa$ . This is made evident by the fact that  $N_{\kappa n} = 0$ , when  $\kappa$  is even and  $n$  is odd, or *vice versa*.

If the value of  $I$  is determined by Equation (26), the integrals,

$$\int_0^l f(x) \sin \frac{n \pi x}{l} \sin \frac{\kappa \pi x}{l} dx$$

\* When  $\alpha = 0$ ,  $m = 1$ , and  $n = \kappa = \pm 1$ , the right side of Equation (32) assumes the indeterminate form,  $\frac{0}{0}$ , the limiting value of which is 0.

(in which,  $\kappa$  and  $n = 1, 2, 3, \dots n$ ), would appear in Equation (33). In many cases, for instance, when  $f(x)$  is a polynomial or an exponential function, it is possible to solve them exactly, but generally they can be determined easily by some approximate method.

The theory herein presented may be applied to the numerical example given by the author, except that the moment of inertia diminishes, according to Equation (25), to one-half the given value at the support.

First, compute the coefficients,  $b_n$ . In the given case it will be easier to use, not Equation (28), but the known equation:

$$\frac{d^2 M}{dx^2} = -q \dots \dots \dots (38)$$

in which,  $M$  is the bending moment of the truss, and  $q$  is the load. In this specific example,  $q = p - \beta w$  when  $0 \leq x \leq \frac{l}{4}$  and  $q = -\beta w$  when  $\frac{l}{4} \leq x \leq l$ .

Expanding  $q$  into a trigonometric series and integrating twice (see Equation (38)):

$$M_x - \beta H_w y = \sum_1^\infty \frac{2l^2 \left\{ p \left( 1 - \cos \frac{n\pi}{4} \right) - \beta w [1 - (-1)^n] \right\} \left( \sin \frac{n\pi x}{l} \right)}{\pi^3 n^3} \dots (39)$$

Then, from Equation (36):

$$C_n = \frac{2l^2 \left\{ p \left( 1 - \cos \frac{n\pi}{4} \right) - \beta w [1 - (-1)^n] \right\}}{H_w (1 + \beta) \pi^3 n^3} \dots \dots \dots (40)$$

The author has demonstrated that, in order to determine  $\eta$ , it will be sufficient to restrict the expansion of Equation (29) to four terms so that in Equation (37), the value of  $\gamma$  is 4. It is almost evident from the mechanical calculations that the deflection curve can be represented in the form of four sinusoids. Using the data suggested by the author, Equation (37) becomes:

$$\left. \begin{aligned} a_1 + \mu \left( \frac{81}{64} a_1 - \frac{27.81}{16.140} a_3 \right) &= C_1 \\ a_2 + \mu \left( -\frac{162}{35} a_2 - \frac{81}{40} a_4 \right) &= C_2 \\ a_3 + \mu \left( -\frac{243}{16.140} a_1 + \frac{81^2}{640} a_3 \right) &= C_3 \\ a_4 + \mu \left( -\frac{81}{100} + \frac{32.81}{143} a_4 \right) &= C_4 \end{aligned} \right\} \dots \dots \dots (41)$$

From this point the solution is not difficult and, therefore, does not need to be presented. Its application to the particular case presented by the author, namely, to find the corresponding values of  $p$  when  $\beta = 0.2$ , is as follows: Calculating the value of  $p$  from Equation (34), the values of  $a$  in

Equation (41) can be easily found in terms of  $C$ , by making the proper substitutions and solving simultaneous equations. The results are:

$$\left. \begin{aligned} a_1 &= 0.6944 C_1 + 0.0517 C_2 \\ a_2 &= 0.3842 C_2 + 0.0371 C_4 \\ a_3 &= 0.0057 C_1 + 0.2184 C_3 \\ a_4 &= 0.0093 C_2 + 0.1370 C_4 \end{aligned} \right\} \dots \dots \dots (42)$$

In order to make the remaining calculations shorter, it is best to introduce the quantities:

$$\kappa = \frac{2 l^2}{H_w (1 + \beta) \pi^3} = 21.99 \dots \dots \dots (43)$$

$$C_n = \kappa C_n' \dots \dots \dots (44)$$

$$a_n = \kappa a_n' \dots \dots \dots (45)$$

Then, by making proper substitutions in Equation (40) values of  $C$  are determined as follows:

$$\left. \begin{aligned} C_1' &= \frac{0.2929 p - 2 \beta w}{1} \\ C_2' &= \frac{p}{8} \\ C_3' &= \frac{1.7071 p - 2 \beta w}{27} \\ C_4' &= \frac{p}{32} \end{aligned} \right\} \dots \dots \dots (46)$$

Consequently, according to Equation (42):

$$\left. \begin{aligned} a_1' &= 0.2067 p - 1.621 \\ a_2' &= 0.0492 p \\ a_3' &= 0.0155 p - 32.126 \\ a_4' &= 0.0054 p \end{aligned} \right\} \dots \dots \dots (47)$$

In the author's Equation (18), substitute the values of  $a_n$  found by Equations (45) and (47) and also the other numerical values given; then the value of  $p$  will be found equal to 7 937 lb. per lin. ft. = 661.5 lb. per lin. in. Beyond this point the solution is exactly as given by the author.

As a second example, consider the same bridge, assuming that  $I_1 = 0$  and that  $\beta = 0.2$ , as before. In Equation (25), since  $\alpha = 0$  and  $m = 1$ :

$$I = I_0 \sin \frac{\pi x}{l} \dots \dots \dots (48)$$

Then, following the same procedure as in Equation (46):

$$\left. \begin{aligned} C_1 &= 1.404 a_1 - 0.727 a_3 \\ C_2 &= 2.294 a_2 - 1.479 a_4 \\ C_3 &= -0.081 a_1 + 3.850 a_3 \\ C_4 &= -0.370 a_2 + 5.930 a_4 \end{aligned} \right\} \dots \dots \dots (49)$$

and,

$$\left. \begin{aligned} a_1' &= 0.221 p - 1.692 \\ a_2' &= 0.0653 p \\ a_3' &= 0.021 p - 58.7 \\ a_4' &= 0.0098 p \end{aligned} \right\} \dots \dots \dots (50)$$

The author's Equation (18) will then become:

$$0.266 \times 10^{-5} p^2 + 0.199 p - 1689.4 = 0$$

$$p = 7700 \text{ lb. per lin. ft.} = 642 \text{ lb. per lin. in.}^*$$

Comparing these values of  $p$  (661.5 and 642) with those determined by the author for a truss with a constant rigidity ( $p = 671 \text{ lb. per lin. in.}$ ), will show that the magnitude of the load necessary to cause a definite increase,  $H$ , in the stress,  $H_w$ , will diminish very slowly with a decrease in the rigidity of the truss. When the moment at the support is reduced one-half, the value of  $p$  decreases only 9.5 lb. per lin. in., whereas when the moment at the support is zero, the decrease is 29 lb. per lin. in. (A somewhat greater decrease would be obtained if a less favorable curve than that described by Equation (25) were assumed.) In other words, the horizontal component as well as the total tension in the cable increases under the action of a given temporary load at a rate considerably slower than the corresponding decrease in the rigidity of the truss. This result may interest the bridge engineer, because it will, perhaps, allow a more rational construction of the stiffening truss.

GEORGE C. PRIESTER,\* ESQ. (by letter).—The application of a trigonometric series to a deflection problem is so advantageously presented in this paper that it is desirable to discuss the problem of the stiffened suspension bridge in more detail.

The writer presents an extension of this problem in the following studies: (a) The relation between the additional horizontal component of cable stress and live load; (b) the application of the live load in two increments; (c) the solution of a problem when the cable is attached to the towers; and (d) the effect of a concentrated load on the span. The notations used are the same as those in the paper:

*The Relation Between  $\beta$  and  $p$ .*—Since  $p$  represents the live load per unit length over a part or all of the truss, and  $\beta = \frac{H}{H_w}$ , the relation between these two values will be used in terms of numerical quantities. For this problem the relation between  $p$  and  $\beta$  will be investigated for a three-span suspension bridge with the cable free to move over the towers. It will be assumed that the live load covers the main span from  $x = 0$  to  $x = \frac{l}{4}$ ; that there is no live load on the side spans; and that the temperature is  $55^\circ \text{ Fahr.}$  above normal. The other numerical data for this problem are those of the Manhattan Bridge as given by the author.

In order to solve the numerical computations it is desirable to assume values for  $\beta$  in Equation (22) and compute  $p$ . This will be done in various ways: First, by assuming the load and temperature to act simultaneously, that is, by using the complete equation; second, by assuming the same values for  $\beta$  and the temperature to be normal; and third and fourth, to carry out the same computations by omitting the terms involving the square of the coefficients,  $a_n$  and  $b_n$ , for the first and second case. The values of  $p$  obtained

\* Associate Prof., Mathematics and Mechanics, Univ. of Minnesota, Minneapolis, Minn.

by the first and second method will be called  $p$  (exact) in contrast with those obtained by the third and fourth method in which they will be called  $p$  (approximate). The  $p$  (approximate) values correspond to those obtained by the deflection method, since the original assumptions in the development of the equations for these two cases are identical. The results for these conditions are given in Table 1.

TABLE 1.—VARIATION OF  $p$  AND  $\beta$ . WITH AND WITHOUT TEMPERATURE  
(THREE SPANS).

$\beta$ .	$p$ (exact) $t = 55^\circ \text{ Fahr.}$	$p$ (exact) without allowing for temperature.	Difference.	$p$ (approximate) $t = 55^\circ \text{ Fahr.}$	$p$ (approximate) without allowing for temperature.	Difference.
0.05	277.1	196.1	81.0	280.0	197.2	82.8
0.10	474.3	391.8	82.5	481.2	395.7	85.5
0.20	866.5	781.5	85.0	887.5	797.0	90.5
0.40	1 641.0	1 552.0	89.0	1 717.0	1 616.0	101.0

It will be noted that the values in the "Difference" columns increase with an increase in  $\beta$ . This is to be expected since the term in Equation (22) which takes into account the effect of temperature is of the form,

$$H_w \left( 1 + \frac{\beta}{2} \right) \propto t L_t$$

and an increase in  $\beta$  will increase the effect of a given temperature.

It should be noted that there is a slight deviation from a linear proportionality between  $p$  and  $\beta$ . Since this deviation is small it is possible to assume a linear relation for small increments of  $\beta$ .

*The Live Load Applied in Two Increments.*—In the development of Equation (22) the average load,  $w + \frac{q}{2}$ , was assumed to be acting through the distance,

$\eta$ , in calculating the work done. A numerical example will show that this assumption may be used. Since a simple problem will suffice, it will be assumed that the suspension bridge consists of only one span and that the cables are fastened rigidly at the towers. The data of the main span of the Manhattan Bridge will be used. For numerical computation two-increment loading is chosen. The live load,  $q$ , acting on the cable will be divided into two parts. In the first increment the average load acting on the cable will

be  $w + \frac{q_1}{2}$ , and, in the second increment,  $w + q_1 + \frac{q_2}{2}$ . The deflection of the truss for the first increment of loading will be designated by  $\eta_1$ , and that for the second increment by  $\eta_2$ . Also, let  $H_1$  equal the additional horizontal component of cable stress due to the first increment; and  $H_2$ , that for the second increment of loading. Then,  $\beta_1 = \frac{H_1}{H_w}$  and  $\beta_2 = \frac{H_2}{H_w + H_1}$ .

For the first increment of loading the equation for determining  $H_1$  is:\*

$$\frac{H_w^2 L}{A E} \beta_1 \left(1 + \frac{\beta_1}{2}\right) = \frac{2 w}{\pi} \left(1 + \frac{\beta_1}{2}\right) \left(a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots\right) \\ + \frac{\pi^2 H_w}{4 l} (1 + \beta_1) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots \dots (51)$$

and for the second increment of loading, the equation for determining  $H_2$  is:

$$\frac{H_w^2 (1 + \beta_1^2) \beta_2 \left(1 + \frac{\beta_2}{2}\right) L}{A E} \\ = \frac{2 w l}{\pi} (1 + \beta_1) \left(1 + \frac{\beta_2}{2}\right) \left(a_1' + \frac{1}{3} a_3' + \frac{1}{5} a_5' + \dots\right) \\ + \frac{\pi^2 H_w}{4 l} (1 + \beta_1) (3 + 2 \beta_2) \left((a_1')^2 + 2^2 (a_2')^2 + 3^2 (a_3')^2 + \dots\right) \dots (52)$$

in which,

$$a_n' = \frac{2 l^4}{E I \pi^5} \frac{p \left(\cos \frac{n \pi a}{l} - \cos \frac{n \pi b}{l}\right) - \beta_2 (1 + \beta_1) w (1 - \cos n \pi)}{n^5 + n^3 \alpha (1 + \beta_1) (1 + 2 \beta_2)} \dots (53)$$

For  $\beta_1 = 0.10$ , the value of  $p$  from Equation (51) is 338.2 lb. per lin. in. and, for  $\beta_2 = 0.10$ , the value of  $p$  from Equation (52) is 368.0 lb. per lin. in. The load which will produce an additional horizontal component of cable stress corresponding to  $\beta_1 + \beta_2$  will be the sum of  $p_1$  and  $p_2$ , or 706.2 lb. per lin. in.

Since it is necessary to determine whether a single loading will produce the same effect as the two-increment loading, a single value of  $\beta$  ( $= 0.21$ ) must be used, which is equivalent to  $\beta_1 + \beta_2$ . Then (Equation (51)), the value of  $p$  is 706.0 lb. per lin. in. This agrees with the value of the sum of  $p_1$  and  $p_2$  when the load is applied in two increments. For a second illustration of this problem assume that  $\beta_1 = \beta_2 = 0.20$ . When  $\beta_1 = 0.20$ , the value of  $p_1$  is found to be 673.0 lb. per lin. in. by the use of Equation (51). With  $\beta_2 = 0.20$  for the second increment, the value of  $p_2$  is found to be 790.0 lb. per lin. in., by the use of Equation (52). The sum of  $p_1$  and  $p_2$  is 1463.0 lb. per lin. in. The value,  $\beta = 0.44$ , corresponds to  $\beta_1 + \beta_2 = 0.40$ . From Equation (51) for  $\beta = 0.44$ ,  $p$  is 1461.0 lb. per lin. in. Thus, it is shown that by the use of the average load,  $w + \frac{q}{2}$ , a sufficiently accurate value of the cable stress is found.

*An Analysis of Stress with the Cable Fixed at the Towers.*—When the cable for a three-span suspension bridge is fixed at the towers, as in the case of the Delaware River Bridge, the deflection of the towers must be taken into account when a live load or a temperature change is acting on the structure. The equations necessary for the computation of the value of  $H$  for a symmetrically placed load and equal side span will be given. (Similar equations can be developed when these conditions are not symmetrical.)

\* The development of the equations used in this discussion and a more detailed study of the suspension bridge are published in "Application of Trigonometric Series to Cable Stress Analysis in Suspension Bridges," by George G. Priester, M. Am. Soc. C. E., *Engineering Research Bulletin* No. 12, March, 1929, Univ. of Michigan, Ann Arbor, Mich.

Since the towers are bent by a change in the cable stress and since the stress in the cable over the side span is different from that in the main-span cable, it is necessary to have an equation for the side span, one for the main span, and one for the deflection of the towers.

Besides the notations previously given, it is necessary to use the following:

$H_1$  = the additional horizontal component of stress in the cable of the side spans.

$\delta$  = the deflection of the towers.

$I_t$  = the moment of inertia of a cross-section of the tower about the axis perpendicular to the plane of bending.

$h$  = the height of the tower.

$S$  = the vertical component of the total cable stress.

$$\beta_1 = \frac{H_1}{H_w}$$

$$L_{1s} = \int_0^{l_1} \left( \frac{d s_1}{d x} \right)^2 d s_1$$

$$L_{1t} = \int_0^{l_1} \left( \frac{d s_1}{d x} \right) d s_1$$

The equation of equilibrium for the side span is:

$$\begin{aligned} & \frac{H_w^2}{A E} \left( 1 + \frac{\beta_1}{2} \right) \beta_1 L_{1s} + H_w \left( 1 + \frac{\beta_1}{2} \right) (\omega t L_{1s} - \delta) \\ &= \frac{2 w_1 l_1}{\pi} \left( 1 + \frac{\beta_1}{2} \right) \left( b_1 + \frac{1}{3} b_3 + \frac{1}{5} b_5 + \dots \right) \\ &+ \frac{\pi^2 H_w}{2 l_1^2} (1 + \beta_1) (b_1^2 + 2^2 b_2^2 + 3^2 b_3^2 + \dots) \dots \dots \dots (54) \end{aligned}$$

and for the main span:

$$\begin{aligned} & \frac{H_w^2}{A E} \left( 1 + \frac{\beta}{2} \right) \beta L + H_w \left( 1 + \frac{\beta}{2} \right) (\omega t L + 2 \delta) \\ &= \frac{2 w l}{\pi} \left( 1 + \frac{\beta}{2} \right) \left( a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots \right) \\ &+ \frac{\pi^2 H_w}{2 l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots \dots \dots (55) \end{aligned}$$

The equation for the deflection of the towers is:

$$\delta = \frac{H - H_1}{E} \int_0^h \frac{y^2}{I_t} dy \dots \dots \dots (56)$$

As an example, the data taken from the Final Report of the Board of Engineers to the Delaware River Bridge Joint Commission will be used to determine the values of  $H$ ,  $H_1$ , and  $\delta$ . It will be assumed that a live load of 12 000 lb. per lin. ft. extends over the entire length of the main span and that there is no load on the side spans. The temperature is assumed to be 55° Fahr. above normal.

Substituting the proper numerical data in Equations (54), (55), and (56):  $H = 9\,588\,000$  lb.,  $H_1 = 9\,391\,000$  lb., and  $\delta = 19.90$  in. The value of

$H$  which corresponds to the load of 12 000 lb. per lin. ft. is given in the aforementioned report as 9 620 000 lb. and the total movement of the tower as 20.04 in. It is evident, therefore, that the trigonometric-series method can also be adapted for computing the horizontal component of cable stress when the cable is attached at the top of the towers.

*A Concentrated Load on the Span.*—To simplify the calculation of the stresses in the truss of a suspension bridge it is desirable to set up an equation which gives the effect of a concentrated load on the additional horizontal component of cable stress and construct the influence diagrams.

The equation for determining the additional horizontal component of cable stress produced by a concentrated load on the truss is:

$$\begin{aligned} & \frac{H_w^2 L}{A E} \beta \left(1 + \frac{\beta}{2}\right) + H_w \left(1 + \frac{\beta}{2}\right) \omega t L_t \\ &= \frac{2 w l}{\pi} \left(1 + \frac{\beta}{2}\right) \left(a_1 + \frac{1}{3} a_3 + \frac{1}{5} a_5 + \dots\right) \\ &+ \frac{\pi^2 H_w}{4 l} (1 + \beta) (a_1^2 + 2^2 a_2^2 + 3^2 a_3^2 + \dots) \dots \dots \dots (57) \end{aligned}$$

For this case,

$$a_n = \frac{2 l^4 \frac{n \pi}{l} P \sin \frac{n \pi c}{l} - 2 \beta w (1 - \cos n \pi)}{E I \pi^5 n^5 + n^3 \alpha (1 + \beta)}$$

and the concentrated load,  $P$ , is at a distance,  $c$ , from the left end of the span.

As an example, Equation (57) will be applied to the calculation of the additional horizontal component of cable stress for the data of the Manhattan Bridge, with the main span regarded as a single span. The concentrated load,  $P$ , will be taken as 100 000 lb. and the temperature as normal ( $t = 0$ ). The position of  $P$  will be assumed at various points of the span so that its effect when located at any point in the span may be determined from a diagram. The values of  $H$  for various locations of  $P$  are given in Fig. 6. With the aid of this diagram, the value of  $H$  may be determined approximately for any uniformly distributed load and the influence lines for the bending moment in the truss may be drawn.

As an illustration, it will be assumed that the uniform load extends over the left quarter of the span. It is only necessary to regard the concentrated load,  $P$ , as a unit load and then the area bounded by the curve for  $H$ , the  $x$ -axis, and the ordinates limiting the distribution of the uniform load will equal the component of cable stress for a uniformly distributed load of unit intensity. For an approximation of the area under the curve (Fig. 6)  $OBC$  will be regarded as a triangle and  $BCDE$  as a trapezoid. The combined area will equal:

$$K = \frac{0.732 \times 180.9}{2} + \frac{(1.335 + 0.732) \times 180.9}{2} = 253.1$$

For a uniform load of 4 000 lb. per lin. ft., the value of the additional horizontal component of cable stress will be,  $H = 253.1 \times 4\,000 = 1\,012\,000$  lb. For similar conditions the value of  $H$  as computed by Equation (51) is 1 032 000 lb.

The error involved in using this simple approximate method is less than 2 per cent. Thus, it is evident that it may be used to determine a good approximation of the cable stress,  $H$ , or the preliminary values of  $\beta$  when the exact method is used for calculating  $H$ .

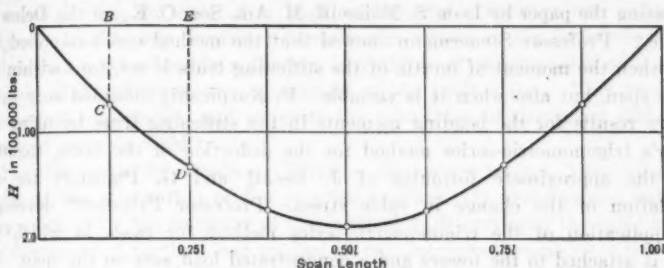

FIG. 6.

The trigonometric-series method can be used to construct the influence lines and diagrams for the bending moment in the truss. If the bending moment is written as follows:\*

$$M = \left( \frac{M'}{y} - H \right) y \dots \dots \dots (58)$$

in which,  $y$  is the ordinate of the cable when the origin is taken at the top of the tower, then the influence line for  $\frac{M'}{y}$  may be drawn in the same manner as

the influence line is drawn for a simple beam (see Fig. 7). Also, from Fig. 6, the influence line for  $H$  can be drawn. The area between these two lines represents the influence diagram from which the bending moment due to a uniform load extending over any part of the span may be obtained. The

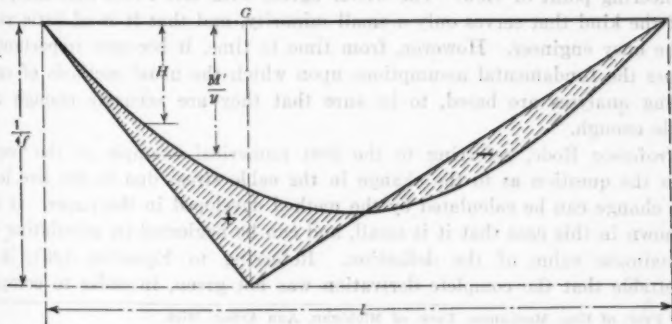

FIG. 7.

shaded area in Fig. 7 represents the influence diagram when the unit load is at the point,  $G$ . This method can be used for determining the most unfavorable positions of the live load in calculating the stresses in the truss.

S. TIMOSHENKO,\* Esq. (by letter).—The advantages of applying trigonometric series to the investigation of cable stresses in suspension bridges were confirmed in several papers published during 1928. Martin† proposed this method independently at about the same time as the writer, and used it in discussing the paper by Leon S. Moisseiff, M. Am. Soc. C. E., on the Delaware Bridge.‡ Professor Steuermann showed that the method can be applied not only when the moment of inertia of the stiffening truss is constant within the entire span, but also when it is variable. F. Karpinski§ obtained very satisfactory results for the bending moments in the stiffening truss by using the writer's trigonometric-series method for the deflection of the truss, together with the approximate formulas of J. Resal|| and G. Pigeaud¶ for the calculation of the change in cable stress. Professor Priester\*\* developed the application of the trigonometric-series method for cases in which the cable is attached to the towers and a concentrated load acts on the span. On the basis of this work, he concludes that the numerical calculations in the "trigonometric-series method" are simpler than those in the "deflection method."

In discussing the paper, Mr. Frost concludes that the practical value of the proposed method as a means of lessening the work is somewhat doubtful since it "is of little value to the busy engineer in the practice of his profession." The writer must apologize if the title of the paper seems misleading, or suggests the advisability of applying his method to the preparation of cost estimates. The intention was to develop a method of analyzing cable stresses in suspension bridges without involving some of the arbitrary assumptions of the usual method, and, at the same time, introducing one that would be simple enough for practical application. The fact that a more rigorous solution is obtained with less work, justifies the application of series from the engineering point of view. The writer agrees with Mr. Frost that the paper is of the kind that serves only a small minority, and that it is of little value to the busy engineer. However, from time to time, it becomes important to discuss the fundamental assumptions upon which the usual methods of engineering analyses are based, to be sure that they are accurate enough and simple enough.

Professor Rode, referring to the first numerical example of the paper, raises the question as to the change in the cable stress due to the live load. This change can be calculated by the method developed in the paper. It can be shown in this case that it is small, and can be neglected in calculating the approximate value of the deflection. Referring to Equation (23), it is regrettable that the complete derivation was not given, in order to compare

calculations made on the basis of the usually accepted Equation (4) with those made from Professor Rode's more accurate equation.

The discussion of Professor Steuermann represents a very interesting development of the proposed Fourier series method. It is shown by using this method that the case of a truss with variable rigidity can easily be analyzed. In this way Professor Steuermann arrives at the interesting conclusion that a considerable reduction in rigidity at the supports of a truss has only slight effect on the magnitude of the cable stress. This result is of practical importance, and suggests the advantage of designing stiffening trusses of variable rigidity.

The discussion by Professor Priester represents several interesting examples of the application of the proposed method. It contains also calculations which prove the accuracy of this method in determining the cable stress. The discussion of the live load applied in two increments establishes the error which may be expected in applying the principle of superposition in discussing such structures as suspension bridges. The stress analysis with the cable fixed at the towers gives a simple solution in the form of a series to a problem which was formerly solved only by the tedious "cut and try" method. By using the series method, Professor Priester also obtained the influence lines for the cable stress and for the bending moments. These permit the determination of the most unfavorable loading for each cross-section of the truss.

### THE ISTHMIAN CANAL SITUATION\*

BY HANS KRAMER,† ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLIAM B. LANDRETH, EDUARDO ICAZA,  
AND HANS KRAMER.

#### SYNOPSIS

General interest in needs for additional Isthmian canal facilities has been actively renewed. The factors which limit the capacity of the Panama Canal and the criteria upon which a forecast of the probable traffic increase is made, form the bases for a graphical method for predicting the saturation point of the existing installation. The conclusion is reached that the Panama Canal (augmented by the pending Alhajuela Reservoir development) will be adequate to handle all probable traffic until 1970.

The choice for additional facilities to be provided to meet future traffic needs is limited to the construction of additional locks at Panama and the opening of a new canal route *via* Nicaragua. The relative advantages and disadvantages of these alternatives are discussed from the present-day viewpoint. From this comparison, the installation of more locks at Panama is the logical method for supplying future needs for additional Isthmian canal facilities.

Neither the necessity nor advisability of a Nicaragua Canal appears to exist at present.

Newspapers, popular periodicals, and technical journals have contained numerous references in recent months to the impending inadequacy of the

\* This paper was written in May, 1927, and, therefore, is based on data obtainable at that time. Inasmuch as this study presents, in part, a prediction as of May, 1927, it has not been deemed desirable to modify the original manuscript by including developments of a later date. Published in August, 1928, *Proceedings*.

† Lieut., Corps of Engrs., U. S. A., Fort du Pont, Del.

Panama Canal and to the necessity of additional Isthmian canal facilities, the latter preferably by way of Nicaragua. The agitation by feature writers and editors has been augmented by the public utterances and recommendations of Congressmen and public officials.

In view of the sudden revival of public interest in a problem which has enjoyed a well-earned rest for more than a decade, it seems pertinent to raise several fundamental questions on which the present and any future discussion properly ought to be based. First, when will the maximum capacity of the Panama Canal probably be reached? Second, what additional facilities will then be advisable? In general, the various recent statements have been predicated on the hypothesis that the capacity of the Panama Canal has already been reached, or that it will be reached in the very near future, and that, therefore, the second question of additional canal facilities is of immediate importance.

It is the purpose of this paper to develop the answers to these basic questions utilizing cold-blooded statistics, established facts, and the opinions of recognized experts. Except where necessary for this purpose, no descriptive matter will be included; the written works of the builders of the Panama Canal have incomparably covered this aspect. A general familiarity with the existing canal is, therefore, assumed.

#### FORECAST—TIME OF REACHING CAPACITY

When will the maximum capacity of the Panama Canal probably be reached?

Varying arguments have been introduced to show the necessity for additional Isthmian canal facilities. Some of these have been directly stated, others only implied. All the pertinent points, however, can be readily classified. It seems sufficient to group these arguments in two main categories—technical reasons and non-technical reasons. The latter designation is used for convenience and is not intended to be derogatory. In fact, some of these non-technical considerations may be of greater importance than the technical ones.

*Technical and Non-Technical Arguments.*—The technical arguments that should receive primary attention are those that portend an early inadequacy of the present Panama Canal to handle the traffic offered. Such inadequacy would be evidenced by congestion due to excessive quantity of traffic or by inability to handle vessels of excessive dimensions.

The leading argument in the non-technical group is linked with the question of National defense. The American fleet has been taken expeditiously through the Panama Canal several times. A similar canal at Nicaragua, nearer Mexico and nearer the United States, with new naval bases as an integral part of the development, would undoubtedly add to the efficacy of these naval forces. But is this necessary? The opening of new Central American markets and outlets for Central American products by way of a Nicaraguan Canal is another non-technical argument (emanating undoubtedly from political, business, and banking interests), for early commencement of canal construction in Nicaragua. Out of this argument grows another—that such an

enterprise would stimulate business through the circulation of a large part of the surplus of the United States Treasury. The proponents of this particular argument may also have in mind the utilization of the Treasury's selfsame surplus to meet deficits during the long lean years before another canal becomes self-sustaining.

Some statesmen are probably hoping to make political capital out of their alertness and sagacity in being among the first to urge the construction of another or a bigger Isthmian canal. Others—perhaps more sincere, more altruistic, more philanthropic—see in a new canal *via* Nicaragua, not only the solution of the present vexing Nicaraguan question, but the settlement of the whole Central American political and economic problem for all time. All these are grouped as non-technical reasons to show the necessity for additional canal facilities.

*Present Operating Capacity.*—In approaching the basic question as to just when the capacity of the existing canal will be reached, it is relevant to ask the preliminary question: What is the capacity of the present canal and how is this capacity determined and limited? Concise and authoritative data on this question are given\* by Brig. Gen. M. L. Walker, U. S. A., Governor of the Panama Canal, which statements form the basis of the present conclusions, and, therefore, require no further proof for their authenticity and reliability.

The limiting factors at Panama are the operating speed of the locks, their dimensions, and the water supply for maintaining the level of the summit lake. Without going into the details of mathematical computations of speed of lock operation, suffice it to say that the original designers conservatively estimated† that the Panama Canal would be able to handle 80 000 000 net tons of shipping per year. This estimate contemplated 24-hour per day operation, allowing ample shut-downs for periodic repair and overhaul. Actual experience has borne out the correctness of this estimated maximum tonnage capacity.

Each lock at Panama has usable clearances of 1 000 ft. of length, 110 ft. of width, and 40 ft. of depth. For commercial purposes these dimensions are ample. The general tendency in the design of commercial vessels shows a departure from the *Leviathan* type for reasons that are not essential to this discussion. The Washington Conference placed a "damper" on competitive naval armament and the consequent development of super-dreadnought sizes. Had the pre-war rate of growth of battleship dimensions continued without abatement the limiting size of the Panama locks would soon become a serious consideration. Therefore, the construction of both commercial and naval ships of such a size as would prevent their transit appears at present to be only a remote possibility.

*Water Supply as a Limiting Factor.*—The other physical factor affecting the capacity of the Panama Canal is the water supply for maintaining the level of Lake Gatun at a height to afford ample depth of channel through the summit section of the canal. As is well known the rainfall in that drain-

\* "The Panama Canal After Ten Years", *The Military Engineer*, May-June, 1925.

† "The Panama Canal," by Messrs. Bakenhus, Knapp, and Johnson.

age area is not ideally distributed throughout the year. The supply is ample in gross quantity, but is so distributed as to provide an excess of water during the rainy season and, generally, a shortage during the four months of the dry season. In other words, the result is that the maximum amount of traffic can always be accommodated during the rainy season—water is sufficient for all lockages—but it may be limited during the dry months. It has been estimated reliably that with even the driest of dry seasons, the existing canal facilities can accommodate from 30 000 000 to 40 000 000 tons of shipping per year without interruption of service.\*

Contrary to current popular belief, this limitation is not a new discovery, nor an evidence of improper design and lack of forethought on the part of the builders. Neither is it a serious menace to the continued operation of the canal under any conditions of traffic which have been encountered to date. The characteristics of the rainfall in the Lake Gatun area were well known and fully considered when the canal was designed. It was realized that construction of an additional dam to create another storage reservoir in the Chagres River Valley above Lake Gatun would be necessary before the ultimate capacity of the canal as determined by the maximum number of lockages could be utilized. Accordingly, hydrological and other data have been compiled for years in anticipation of the inevitable dam and reservoir construction at Alhajuela, Panama, just outside (east of) the Canal Zone.

The expected traffic in the early years of operation did not require the additional storage basin for maintaining the lake level, so that this development was very wisely left for later years. Since annual traffic is now approaching the expected stage, and since no reasons exist for believing that the Panama seasons will change their rainfall characteristics, it is now advisable and justifiable to appropriate funds for the long considered Alhajuela Dam construction.† Other benefits, such as hydro-electric power, would also result from this project, which involves no particularly difficult engineering problems. Four or five years' time for construction and an expenditure of \$10 000 000 to \$15 000 000 will insure the continued operation of the canal under the maximum traffic load of 80 000 000 tons annually, regardless of the fluctuations of the rainfall.‡

*Records of Panama Traffic.*—Having analyzed the physical factors which limit the capacity of the Panama Canal, the next logical step is to review the history of canal traffic. Table 1, from the official records of the Panama Canal, shows the amount of shipping in net tons through the canal during each calendar year since its opening. These data do not include U. S. Naval vessels and miscellaneous craft exempt from tolls. It is obvious that, during the year of heaviest traffic to date (1927), the 26 600 000 tons taxed the canal capacity to about one-third of its maximum of 80 000 000 tons per year. This

\* "The Construction of the Panama Canal," by Sibert and Stevens.

† The 1929 Army Appropriation Bill, H. R. 10 286, approved March 23, 1928, contains the following item:

"\$250 000 for commencing the construction of a dam across the Chagres River at Alhajuela for the storage of water for use in the maintenance and operation of the Panama Canal, together with a hydro-electric plant, roadways, and such other work as in the judgment of the Governor of Panama Canal may be necessary, to cost in the aggregate not to exceed \$12 000 000."

*Bulletin.* The source of the world commerce figures is the Statistical Abstract compiled annually by the U. S. Department of Commerce.

The statistics of Tables 1 and 2 (Panama traffic, Suez traffic, and world commerce) are charted and presented graphically in Fig. 1. The salient points should be noted—the apparent smoothness and gradual upward increase of Suez traffic (Curve A) from the opening of the canal in 1870 until the beginning of the World War in 1914; the world commerce curve (Curve B), similarly smooth and gradually increasing over the same period of time, although of course it does not originate at zero in 1870; the terrific jar to the world's equilibrium caused by the World War and reflected by the extreme peaks and valleys in the curve between 1914 and 1918; the rapid and steady climb in Panama Canal traffic during the canal's first decade of operation, as evidenced by the steep general slope of the Panama curve (Curve C); finally, and interestingly, too, the Panama traffic in 1926, practically equal to the Suez traffic. The vertical scale for charting world commerce having been suitably chosen, all three of the curves under consideration virtually attain a common point in 1926, which, in turn, permits of starting at a common origin in projecting the curves into the future.

\* Estimated; complete official figures for 1926 not available.

Whereas Fig. 1 is an authentic graphic portrayal of official statistics, Fig. 2 is partly authentic, partly artificially manipulated, and partly conjectural. The Suez traffic (Curve A) and the world commerce curve (Curve B) are true copies from Curves A and B of Fig. 1 for the periods 1870 to 1913 and 1921 to 1926. The World War period, including the years

of restoration to normalcy, 1914 to 1920, has been arbitrarily and artificially effaced from Fig. 2 by the simple mechanical expedient of plotting the year 1921 to follow immediately after the year 1913. For convenience a new curve, Curve *D*, has been introduced representing Suez Canal traffic averaged by decades. This smoothes out some of the minor irregularities in the Suez yearly curve. The last decade for Curve *D* also eliminates the World War period and averages the annual traffic for the ten years, 1910 to 1913 and 1921 to 1926, inclusive.

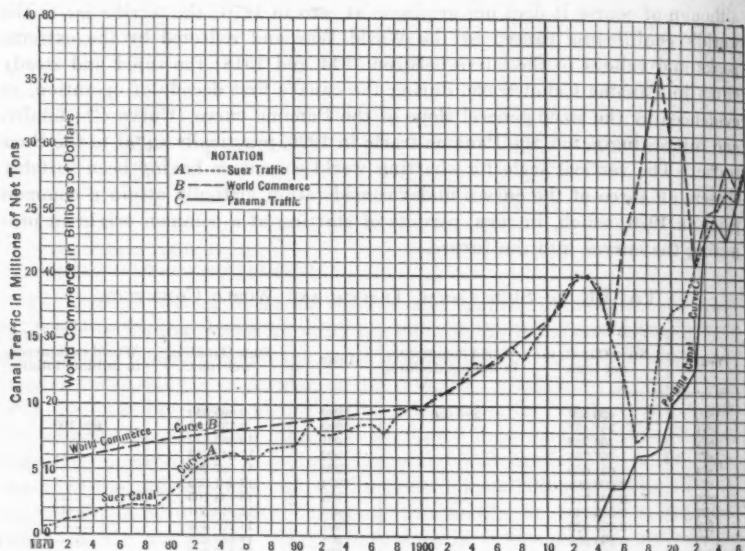

FIG. 1.

*Future Trends.*—Now comes the rub! The prolongation of a known curve into the unknown future is at once a dangerous and difficult undertaking, and, as has often been caustically said, "figures won't lie but liars will figure". The extension of a curve beyond its known values is particularly precarious and its reliability consequently is subject to wide differences of opinion when the length of the projection considerably exceeds the length of the established record. Predicting future behavior over a 5 or 10-year period from a given record of 50 years usually can be done fairly safely. A similar projection of a much shorter curve has many pitfalls; and a 50-year prolongation of a 15-year curve is like shooting at the moon. It can be done, however, and in some respects it is less complicated than making a similar projection for the much shorter 5 or 10-year period.

In attempting to forecast for the next decade a thorough analysis of political, economic, and social conditions throughout the world would be necessary to determine their probable trend and corresponding probable effect on canal traffic. Temporary local disturbances and commercial fluctuations

would have to be carefully studied in a prediction covering only the next few years. However, in considering the next 50 to 100 years, unexpected, unknown, unpredictable factors may arise, such as world-wide disturbances, development of new trade centers and routes, revolutionizing inventions, etc., which events may entirely overshadow the effect of any expected, known, and predictable factors. In this prognosis of canal traffic over a relatively long time, therefore, no attempt is made to analyze or predict the conditions which will affect future Isthmian canal traffic. The forecast is made virtually entirely on the background of established history and tendencies.

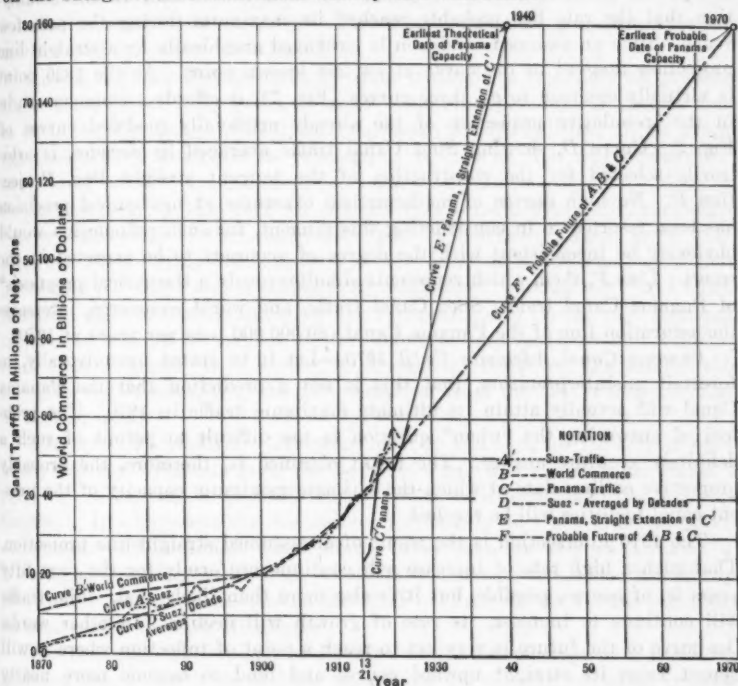

FIG. 2.

*Straight-Line Projection of Traffic Record.*—Referring to Fig. 1, it is evident that a purely theoretical prolongation of the Panama Canal Curve C would be practically a straight line of very steep slope. In Fig. 2 this theoretical extension has been plotted (Curve E). It intersects the upper horizontal line of the graph (the maximum ultimate capacity of the canal) at about 1940. That the traffic through the canal will continue to increase at its past rate so as to reach the saturation point in 1940 seems highly improbable. The creation of new devices usually results in rapid growth of utilization and in every healthy case such growth continues but generally at a more moderate rate after the novelty has worn off. Table 1, in fact, verifies this

general law of behavior as applied to the Panama Canal, for the statistics of traffic since 1923 indicate normal and steady conditions after the rapid increase of the first decade. This theoretical straight-line extension (Curve *E*) of the Panama Canal traffic curve can be interpreted as the extreme condition in growth of traffic which would result in reaching the maximum canal capacity within the next fifteen years, if the rate of increase during the first decade continues—a highly improbable condition.

A condition more likely to prevail over a long period of future growth is that the present annual increment will remain constant, on the assumption that the rate has probably reached its maximum during the past few years. Such an assumed condition is portrayed graphically by a straight-line projection tangent to the curve at its last known point. As the 1926 point is virtually common to all three curves (Fig. 1), it affords a common origin in the speculative projection of the already artificially modified curves of Fig. 2. Curve *D*, showing Suez Canal traffic averaged by decades, is arbitrarily selected for the construction of the tangent straight line, Projection *F*. No high degree of mathematical exactness or mechanical precision has been resorted to in constructing this tangent, for such refinements would obviously be inconsistent with the degree of accuracy to be expected in the result. Line *F*, then, which represents simultaneously a theoretical prognosis\* of Panama Canal traffic, Suez Canal traffic, and world commerce, intersects the saturation line of the Panama Canal (80 000 000 tons per year) at 1970.

*Panama Canal Adequate Until 1970.*—Let it be stated unequivocally, to forestall misinterpretation, that this is not a prediction that the Panama Canal will actually attain its ultimate maximum traffic in 1970. The problem of answering the “when” question is too difficult to permit of such a definitely accurate answer. The result obtained is, therefore, the probably projective earliest date at which the ultimate maximum capacity of the present canal facilities will be reached.

The 1970 intersection is the result of an assumed straight-line projection. That such a high rate of increase will continue uniformly for the next fifty years is, of course, possible, but it is also more than likely that, while traffic will continue to increase, its rate of growth will decline. In other words, the curve of the future is very apt to reach a point of inflection where it will depart from its straight upward course and tend to become more nearly horizontal. This tendency can reasonably be expected in the higher range of the diagram, justifying the inference that the straight-line tangent projection is reasonably conservative in predicting growth over a long period of time. Had the projection been actually made on the true curves of Fig. 1, rather than on the artificial curves of Fig. 2, it is evident that the slope of Curve *F* would have been somewhat nearer the horizontal and there would have been a resultant later intersection with the upper saturation line. This further emphasizes the conservatism of the 1970 intersection.

If the accuracy of established records, the reasonableness of assumptions, and the conservatism of construction methods, are acknowledged, then the

\* Traffic statistics for the calendar year 1927 are as follows:

Panama Canal.....	28 610 984 net tons
Suez Canal.....	28 965 000 net tons

result obtained should be accepted. It is believed that all these various factors have been satisfactorily explained and established. The conclusion therefore is warranted that the Panama Canal (augmented by the justifiable Alhajuela Reservoir development) will probably not be taxed to its maximum capacity within the next forty years, and that it will prove adequate to handle all probable traffic until the calendar reads 1970.

#### PROVISION FOR ADDITIONAL CAPACITY

What additional canal facilities should be provided when the present installation reaches its capacity? This second question is as important as the first and follows it most logically.

Having deduced that the present canal is adequate to handle all probable traffic for at least forty years, it seems somewhat paradoxical at this time to open any discussion of additional Isthmian canal facilities. Even granting that such a discussion is relevant, it is obvious that any comparative analysis of possible expansion projects must be made as of 1927. Many of the factors entering into such an analysis may remain materially unchanged over a long period of time, but others may be markedly altered as to character and effect during the next forty years. Physical conditions may remain practically as they are, but political conditions, particularly in Central America, are constantly changing their complexion. Social and economic factors, too, are not permanent, but are likely to vary in aspect and influence from time to time. In the ensuing discussion, therefore, the unavoidable inconsistency of presenting the 1970 situation from the 1927 viewpoint must be kept in mind.

*Alternative Possibilities.*—However, let it be assumed, for the sake of argument, that the Alhajuela Dam has been built and that the Panama Canal is carrying its maximum load of traffic. What additional facilities are now feasible? In all present-day discussions, fortunately only two alternatives are recognized. All Isthmian canal routes other than by way of Panama or Nicaragua were eliminated from consideration many years ago. Either supplementary sets of locks can be installed at Panama or a new canal can be constructed through Nicaragua.

The expansion at Panama would involve the construction of a third and perhaps, also, a fourth set of locks paralleling the existing twin-lock installation. The effect of such improvement would be the creation of a highway accommodating three or four lines of traffic where only two can flow at present. This enlargement would naturally entail some minor modifications in the adjoining existing structures, but would not involve any duplications or major changes in the other canal essentials, namely, Gatun Lake, the summit pool, Gatun Dam which impounds the lake water, Culebra Cut, the "big ditch" through the Continental Divide, and the terminal harbor facilities at Cristobal and Balboa. With the concurrent development of all feasible plans for increased storage and conservation of water no apprehension need exist as to any probable dry-season water shortage. The Nicaraguan project involves complete new construction starting on the Atlantic side in the vicinity of Greytown or San Juan del Norte, canalizing the San Juan River along

the Nicaragua-Costa Rica border, through Lake Nicaragua, piercing the Continental Divide, and emerging at the Pacific side in the vicinity of Brito.

*Pros and Cons of Panama and Nicaragua.*—The advantages and disadvantages of the Panama and Nicaragua routes were exhaustively studied by the Isthmian Canal Commission and other eminent authorities before the Panama Canal was built. In the present comparative study of the merits of the two practicable expansion projects it is not intended to repeat long extracts from the Commission's authoritative report, nor to re-open the discussion of mooted questions which found their answers in the monumental accomplishments of the late George W. Goethals, M. Am. Soc. C. E., the late General Gorgas, and others. These records, written and physical, speak for themselves. For convenience the comparison of the feasible expansion projects at Panama and Nicaragua has been compiled in simple form in Table 3.

To accord with the classification of reasons in the discussion of the probable time of exhaustion of present facilities the comparative factors in Table 3 are grouped under technical and non-technical headings. The more important of the items will be elaborated. Although the factors listed undoubtedly do not exhaust the entire field, yet they are sufficiently complete for the present purposes. They are, in general, broad enough individually to embrace other incidental considerations and comprehensive enough collectively to cover the essential features.

TABLE 3.—COMPARISON OF EXPANSION PROJECTS.\*

Item. (1)	Panama. (2)	Nicaragua. (3)
<b>Technical:</b>		
Type of canal.....	Lock (85-ft. lake level).	Lock (110-ft. lake level).
Length of canal.....	50 miles.	175 miles ±.
Terminal harbors.....	Excellent.	Pacific, fair; Atlantic, poor.
Navigation.....	Easy.	Difficult.
Length of steam-ship routes offset.	Intercoast somewhat longer.	No advantage for South American trade.
Time of transit.....	6 to 8 hours.	24 to 30 hours.
Earthquakes.....	Not a serious factor.	More serious than Panama.
Construction facilities.....	Excellent existing.	None existing.
Additional capacity.....	40 000 000 to 75 000 000 tons (?).	80 000 000 tons (twin lock) (?).
Cost.....	\$150 000 000 to \$250 000 000 (?).	\$500 000 000 to \$1 000 000 000 (?).
Time to complete.....	5 to 10 years (?).	15 years (?).
<b>Non-Technical:</b>		
Defense—separate.....	Vulnerable.	Vulnerable.
Defense—simultaneous.....		Very difficult.
Central American trade.....	No further effect.	Slight development.
Construction rights.....	Perpetual.	Perpetual.
Political situation.....	Stable.	Unstable.

\* Corroborative evidence of reliability of the comparisons in Columns (2) and (3) can be found in the Official Report of the Isthmian Canal Commission, 1899-1901, and in "Problems of the Panama Canal," by Gen. Henry L. Abbot.

*Comparison of Physical Features.*—Frequent misstatements have been made regarding some of the inherent physical characteristics of the two routes. The Panama Canal, it is well known, is of the lock type with a nominal lake summit level of 85 ft. above the sea. The difference in elevation is overcome by twin flights of three locks at each end. Suitable foundations are known

to be available for the construction of a third set of locks and may exist for even a fourth set. From deep water to deep water at both ends the Panama Canal has a total length of 50 miles, of which 24 miles are through Lake Gatun and 8 miles through Culebra Cut.

The question of lock *versus* sea-level design was widely discussed during Panama Canal construction days; but it applied only to the Panama route. Newspapers and magazines to-day refer nonchalantly to the advantages of a lockless sea-level canal by way of Nicaragua. Such references are little short of absurd. Whereas, the Panama route did originally offer a choice between the sea-level and lock alternatives, the Nicaragua route is universally recognized by the Engineering Profession to be impracticable for anything but the lock type of construction.

Proposed plans for a canal *via* Nicaragua contemplate the utilization of the large existing inland body of water, Lake Nicaragua. This would necessitate the maintenance of a nominal summit lake level of approximately 110 ft. above the sea. At least three steps of locks, as at Panama, and probably four, would be required to negotiate this difference in elevation. The total length of the Nicaragua route is about 185 miles, of which about 100 miles would be along the crooked San Juan River which would require artificial canalization. About 70 miles would be through Lake Nicaragua itself which would include about 20 miles of channel dredged (and continuously maintained) through the soft mud and fine silt in the shallow southwestern part of the lake. The severing of the remaining obstacle, the Continental Divide near the Pacific end, would require a cut perhaps 20 miles in length. This brief summary of the outstanding physical features of the two routes is sufficient to indicate that the Nicaragua project would be an even more stupendous undertaking than the construction of the Panama Canal. This prodigiousness, of course, would be reflected in the ultimate cost of construction.

In comparing the item of terminal harbors Panama possesses a wide advantage. The existing harbors at Cristobal and Balboa are excellent examples of the most modern type of port development. At Nicaragua, two harbors remain to be created. The one at the Pacific end could probably be built at a reasonable cost, but the site on the Atlantic presents unusual natural difficulties both for construction and maintenance.

*Relative Advantages for Navigation.*—The difficulties to be met in actual navigation are an important consideration. The gentle curvature of the channel of the Panama route permits of easy negotiation. The Nicaragua channel would be much more tortuous. The relative lengths of the two channels, has a weighty bearing on the question of navigation difficulties, particularly in view of the necessity for night traffic. Much more severe rainfall than is prevalent in Panama is to be expected in Nicaragua. Then, too, the heavier trade winds and stronger channel currents will be encountered. The navigator's choice would undoubtedly favor Panama.

The most ardent advocates of the Nicaragua route, both past and present, propose, as one of their strongest arguments, the advantage of the Nicaragua route in shortening travel distances (and hence time) between principal ports.

The validity of this argument is, however, more apparent than real. Where differences in distance favoring the Nicaragua route do exist, the apparent advantage is fully compensated by the difference in time required to traverse the canals and the inevitable high difference in insurance rates caused by the difference in navigation risks. As compared to Panama the actual sea distance by way of Nicaragua is 666 statute miles shorter between San Francisco, Calif., and New Orleans, La., and 434 miles shorter between San Francisco and New York, N. Y., a gain in time of approximately 48 hours and 31 hours, respectively, for the average modern steamship. Between the eastern coast of the United States and the western coast of South America—a much frequented trade route—the apparent advantage of shorter distance by way of Nicaragua disappears entirely for the eastern terminus of the Nicaragua route is actually farther from the Atlantic seaboard than the eastern end of the Panama Canal.

The time required for passing through the canals must, of course, be considered concurrently with the relative sea distances. At Panama from 6 to 8 hours are consumed in traversing the Isthmus. Estimates for Nicaragua vary, but the time may be conservatively placed at from 30 to 36 hours without allowing for probable frequent delays caused by forced retarding of operating speeds. The closer comparison of the routes, therefore, on the basis of economy of vessel operation, shows that the merits of the Nicaragua route in this respect are generally over-emphasized.

*Feasibility of Constructions.*—The relative possible effect of earthquakes on structures and excavations along the two routes is not considered of primary importance. At Panama the slides are no longer a problem and earth tremors have never been serious enough to affect other structures. What the history of the Nicaragua route would be in this respect is difficult to divine. The fallacy of a sea-level waterway having been previously shown, the claims for any additional inherent stability and permanency of this type of construction are entirely vitiated. Judging from past records and natural existing conditions along the route a lock canal at Nicaragua would be extremely fortunate to enjoy as uninterrupted an existence as the one at Panama.

The influence of the utter lack of construction facilities, such as a paralleling railroad along the Nicaragua route, is obviously included in the item of cost of the project. It should be noted too that the availability of plant and exact knowledge of working conditions at Panama permit of a cost estimate with a fairly high degree of accuracy, whereas the absence of all such facilities and the uncertainty of working conditions necessarily make the Nicaragua estimates much less reliable.

*Cost Estimates Favor Panama.*—Although specific estimates have been made as to the comparative costs in time and money of the two alternatives, the bases are mysteries. Since the report of the Isthmian Canal Commission in 1901 no further official investigation has been made nor estimate prepared of the Nicaragua project. Neither have any recent official estimates been prepared and published for additional lock construction at Panama. Estimates in the engineering sense generally imply preliminary analyses

without which they are merely guesses. The currently quoted figures are undoubtedly merely offhand guesses which by repetition have been dignified by the appellation, "estimates".

The present lack of prepared estimates applies with equal force to both the Nicaragua and Panama expansion projects. The generally quoted figures are from \$150 000 000 to \$250 000 000 for additional lock construction at Panama and from \$500 000 000 to \$1 000 000 000 for a new canal *via* Nicaragua, with an estimated time of construction of 6 to 9 and 12 to 15 years, respectively. No mention is made of the additional tonnage capacity which will be provided by these expenditures. The amount of such increase will depend largely on the design adopted, but it may be presumed that both projects would provide about 100%, or 80 000 000 tons per year, additional capacity.

A simple attempt may be made to arrive at some estimates of cost slightly more reliable than mere guesses. The method is admittedly crude, but sufficiently satisfactory for the present rough comparative purposes. All details, some of which are of major importance, are purposely omitted from consideration. The report of the Isthmian Canal Commission in 1901, on which the decision between Panama and Nicaragua at that time was finally based, estimated the cost of the Panama project at \$144 000 000 and that of the Nicaragua project at \$190 000 000. As actually built the Panama Canal cost \$347 000 000. By simple proportion, taking into account the depreciation in the value of the dollar, the construction cost in Nicaragua in 1927 can be estimated at \$685 000 000. From the total cost of the Panama Canal it is difficult to segregate the cost of the locks as a separate item, but it approximated \$76 000 000. Again, by simple proportion, a 1927 duplication of the Panama locks can be estimated at \$125 000 000. Regardless of the absolute accuracy of these estimates they undoubtedly indicate the relative costs involved in choosing between the two alternatives.

A cursory summary of the advantages and disadvantages possessed by the two feasible expansion projects, as far as technical aspects are concerned, shows that the balance is decidedly in favor of the Panama alternative. From the unrelenting viewpoint of economics—dollars and cents—the Panama choice appears to be indisputable.

*Non-Technical Arguments.*—In the same way that factors other than technical have a bearing on the necessity for additional canal facilities, they must be given due consideration in comparing the feasible expansion projects. The order of their presentation is no indication of the relative importance of these items, for naturally their weight is neither constant nor commensurable.

Perhaps the most interesting of these items is the question of defense of the two routes. Being fundamentally of the same type of construction, it follows theoretically that in this respect the two alternatives will be equally vulnerable to hostile attack. The one presents perhaps a more concentrated target, the other a more extensive one. Both require fortification and defensive organization on a common scale.

The adage, "It is unwise to carry all your eggs in one basket", has been invoked to catch popular fancy as an argument for a Nicaragua Canal. The appropriateness of the proverb is questionable, however. The Isthmian canal situation is not a question of carrying eggs, but of protecting baskets. It has been found difficult to teach the American people the doctrine of reasonable military preparedness. War correspondents who have witnessed maneuvers in Panama have correctly pointed out the inadequacy of the canal defenses, particularly in their air aspect. The necessity for fortifying another site can hardly be expected to correct existing defects nor to simplify the problems of defense.

A word about commercial prospects: That some impetus to local business will result in the area contiguous to the Nicaragua Canal, if built, is certain. The field of development of Central American trade and industry may seem large, but is generally over-rated. Its possibilities certainly do not, in themselves, warrant any considerable expenditures. The Nicaragua route opens no new important markets or sources of raw material that are not equally served or reached by the Panama route.

*International Factors.*—The final element now deals with political conditions. The stability of the situation in Panama, as a virtual protectorate of the United States, is attested to by its relative tranquillity. The United States has exclusive perpetual canal rights in Panama. Although the United States also has exclusive perpetual rights for the construction of the Nicaragua Canal, obtained by treaty with Nicaragua in 1916 for a consideration of \$3 000 000, the conditions for the Nicaragua route are not so favorable. The San Juan River which is the essential route for the canal between the Atlantic and Lake Nicaragua is along the international boundary between Costa Rica and Nicaragua. The establishment of a Canal Zone as a buffer State under United States jurisdiction would probably be welcomed or opposed by Central American strategists, depending on their motives. By some the construction of a canal *via* Nicaragua may be hailed as a panacea to cure all Central American ailments, but it is doubtful whether it would enjoy a very care-free existence in the troubled times of to-day.

#### CONCLUSION

The study of the predictable future growth of Isthmian canal traffic has indicated that the peak-load capacity of the Panama Canal will probably not be reached until 1970. The current discussions, in Congress and the press, therefore, appear to be a quarter of a century in advance of necessity. Not that foresight is ever to be condemned, but extensive preparations for a situation which may be materially altered by unforeseeable developments seems unjustifiable. Perhaps events to transpire in the future will place a different complexion on both the necessity and the advisability of a Nicaragua Canal. Neither appear to exist at present. In short, the problem belongs to posterity.

## DISCUSSION

WILLIAM B. LANDRETH,\* M. Am. Soc. C. E. (by letter).—The author has done a great service by giving a clear and concise statement of Isthmian Canal conditions. Taking the last four years in Table 1 as fairly typical of the yearly Panama tonnage, the annual percentage of gain or loss is found to be as follows: 1924, 1.30% less than 1923; 1925, 5.95% less than 1924; 1926, 12.60% more than 1925; and 1927, 10.70% more than 1926. On the basis of total tonnage, the four-year gain in 1927 is 15.65% of the 1923 tonnage.

The annual report of the State Superintendent of Public Works for 1927, gives the tonnage of the New York State Barge Canal for 1919 to 1927, inclusive. Making comparisons on the same basis as for Panama, the annual percentage of gain or loss is found to be as follows: 1924, 1.30% more than 1923; 1925, 15.30% more than 1924; 1926, 1.07% more than 1925; and 1927, 8.97% more than 1926. Likewise, on the basis of the total tonnage, the four-year gain in 1927 is found to be 28.69% of the 1923 tonnage.

During the canal season of 1928 the gain over that of 1927 has been 19.58 per cent. While the net tonnage on the Panama Canal is much greater than on the Barge Canal, the total gain on the Panama Canal for 1924 to 1927, inclusive, was 15.65% and on the Barge Canal for the same years it was 28.69 per cent. For two of the years the Panama Canal lost traffic, while the Barge Canal gained for each of the four years.

The Barge Canal passes through a populous section of the State and, therefore, a large number of pleasure boats pass through it. During the 1928 canal season, to October 13, the pleasure boats and their lockages were as shown in Table 4.

TABLE 4.—STATISTICS ON THE NEW YORK STATE BARGE CANAL FOR 1928.

Location.	Number of boats.	Number of lockages.
Near eastern end of Erie Canal.....	2 454	650
Near western end of Erie Canal.....	144	130
Near south end of Champlain Canal.....	1 525	674
North end of Champlain Canal.....	680	305
North end of Oswego Canal.....	251	167
Near north end of Cayuga-Seneca Canal.....	198	135
Total.....	5 259	2 261

Probably 15 000 to 20 000 people find enjoyment on the pleasure boats; the lockages used by them equals that used by several million tons of cargo. One should remember that the Panama Canal can be operated for 12 months each year while the weather prevents the use of the Barge Canal for more than about 60% of the year.

An interesting comparison is made between the Panama and Nicaragua Canals in Table 3, which includes a very concise statement of the

\* Cons. Engr., Schenectady, N. Y.

salient points of the two routes. This table gives the time of transit at Panama as 6 to 8 hours and estimates it for the longer Nicaragua Canal at from 30 to 36 hours. This would mean a rate per mile of from 6.26 to 8.33 hours at Panama and from 4.86 to 5.83 hours at Nicaragua. The vertical rise at Nicaragua is about 30% more than at Panama, and differences in the navigation conditions would tend to make the rate at Nicaragua less than at Panama.

On the Barge Canal the motor ship, *Twin Ports* (259 ft. long, 42 ft. wide, and loaded to a draft of 9 ft.), passed from Waterford to Oswego, N. Y.—a distance of 187 miles—in 39 hours and 22 min., which is an average speed of 4.75 miles per hour. The boat passed through 29 locks and 22 miles of lakes on the trip. Other similar boats have made the trip, going or coming, in 42 hours.

The estimate of from 30 to 36 hours for the transit through the 175 miles at Nicaragua seems to be conservative. The writer believes that the conclusions reached by the author are fair and that the paper will prove of great value, especially to those interested in canals.

EDUARDO ICAZA,\* JUN. AM. SOC. C. E. (by letter).—The author has demonstrated beyond a shadow of a doubt that the logical method of supplying future needs for additional Isthmian Canal facilities (in so far as shipping is concerned) is the installation of more locks at Panama. Table 3 gives an excellent comparison. Under "Feasibility of Constructions", may be added the statement that sanitation in the Panama Canal Zone is more favorable than in any other area in the tropics.

One consideration has been omitted and that is the immediate and urgent need of a permanent non-movable steel highway bridge across the canal. It must not be forgotten that the canal has divided the Republic of Panama in two; that Panama has spent millions of dollars on new roads on both sides of the canal and that at present (1928) the only available means of crossing is (at one's own risk) by means of an inadequate ferry service.

Therefore, the Isthmian Canal situation is not wholly providing for future shipping. This, as the author has aptly stated, is a problem that "belongs to posterity". An important part of the present Isthmian Canal situation is to provide a non-movable bridge across the great waterway.

HANS KRAMER,† ASSOC. M. AM. SOC. C. E. (by letter).—An interesting comparison is drawn by Mr. Landreth which shows the relation between growth of traffic in recent years for the New York State Barge Canal and the Panama Canal. Similar comparisons might be drawn for the Sault Ste. Marie, Kiel, Manchester, and other large ship canals. The Panama and Suez Canals, however, are in a class apart in shortening trade routes by the perimeter of a continent. Hence, in the economic study of probable traffic growth, comparison has been limited to these canals, which alone represent essentially similar conditions.

\* Chf., Div., San. Eng. and Sanitation, Panama, Panama.

† Lieut., Corps of Engrs., U. S. A., Fort du Pont, Del.

Mr. Icaza's suggestion that sanitary conditions in the Canal Zone are more favorable than those in Nicaragua, should be included in Table 3. His point regarding the need for a fixed highway bridge, although it is an important National problem for Panama, is not considered to be directly related to the adequacy of facilities for handling water-borne traffic.

An interesting review and a translation of a part of the writer's paper has been published\* under the title, "Le Trafic Actuel et Futur du Canal de Panama". The review is prefaced by the editorial comment that the writer's conclusion is entirely optimistic. This criticism applies to the writer's prediction of the probable adequacy of the Panama Canal until 1970. In the ensuing French discussion, however, no definite errors of fact or assumption which lead to the 1970 conclusion are adduced to support the sweeping allegation. French engineers, because of de Lesseps' connection with the Panama Canal project, maintain a natural interest in the canal's present and future.

Since the preparation of the paper other reliable opinions have been recorded which tend to bear out the writer's conclusion that the rate of increase in traffic will be more moderate in the future. In testifying before a Subcommittee of the House Committee on Appropriations on December 11, 1928, Harry Burgess, Colonel, Corps of Engineers, U. S. A., M. Am. Soc. C. E., Governor of the Canal Zone, stated that "as nearly as we can tell, the increase will not be more than ten million tons per decade". This forecast is in line with the "constant annual increment" assumption on which Curve *F*, Fig. 2, is based, and is even more conservative than the 12 500 000-ton increase per decade predicted by the curve.

Similar non-alarming conclusions are reached by the Standing Committee on "Maximum Capacity of Panama and Steps Being Taken by Those in Authority for Enlargement of the Canal for Shipping in the Future". This Committee reported† to the Association of Pacific and Far East Ports at its Fifteenth Annual Convention at Los Angeles, Calif., June 28, 1928: (1) That the canal was then being used to only one-third its capacity; (2) that the normal increase was less than 2% per year; (3) that, therefore, the canal would not be taxed to full capacity until about 1958 or later; (4) that the public should trust the Canal Administration to anticipate the need of enlargement or of building another canal; and (5) that the need for such expansion was assuredly far in the future.

The reasonableness of these viewpoints is supported by the actual Panama Canal record of transits for the calendar year, 1928. During this last year the net tonnage transmitted was 28 943 437, an increase of 332 453 tons, or 1.2% more than 1927 and an average increase of 1 553 598 tons per year, or 6.0% per year for the two-year period since 1926. The ordinate for the 1928 abscissa on Curve *F*, Fig. 2, predicts a probable traffic of 28 300 000 tons, which is within 2.1% of the actual record for the latest year.

\* *Le Génie Civil*, October 20, 1928.

† *World Ports*, September, 1928, p. 983.

After considerable debate in both Houses, the Seventieth Congress passed Senate Joint Resolution 117 which was approved March 2, 1929,

“\* \* \* authorizing an investigation and survey for the purpose of ascertaining the practicability and the approximate cost of constructing and maintaining additional locks and other facilities at the Panama Canal, and for the purpose of ascertaining the practicability and probable cost of constructing and maintaining an interoceanic ship canal across the Republic of Nicaragua”.

The Chief of Engineers, under the direction of the Secretary of War, is formulating a policy for the execution of this mission. The forthcoming study should satisfy legislators, agitators, and the general public that there are no serious economic or engineering causes for alarm in the present Isthmian Canal situation.

Paper No. 1734

### CHARACTERISTICS OF CENTRIFUGAL OIL PUMP\*

By MICHAEL D. AISENSTEIN,† Esq.

WITH DISCUSSION BY MESSRS. MORROUGH P. O'BRIEN AND  
MICHAEL D. AISENSTEIN.

#### SYNOPSIS

The use of centrifugal pumps on oil pipe lines and at refineries has been growing. Because they are quantity pumps and have such merits as low first cost, simplicity of operation, steady flow, and adaptability for direct connection to high-speed machinery, centrifugal pumps attract all industries which have to deal with pumping machinery. Whereas the efficiency of a properly designed centrifugal water pump runs very high, this efficiency decreases when the same pump is used in a viscous fluid.

It is evident that, when pumping oil (besides all ordinary mechanical and hydraulic losses, for a viscous liquid), a new loss enters which dominates all the others. This is the viscosity or the internal resistance loss. The effect of viscosity is to decrease the head capacity and to increase the disk friction. This lowers the efficiency of the centrifugal pump correspondingly.

It is important to know the laws which govern the decrease in the head capacity and the increase of horse-power which affect the efficiency of the centrifugal pump. It is also important to know the limiting value of viscosity for each type and size of centrifugal pump at which it is practical to pump viscous oils. Moreover, as it is a comparatively easy matter to test a pump on water, it is of great advantage to have a method by which it is possible to predetermine what a centrifugal pump of known water characteristics will do when pumping a viscous oil.

By characteristics is meant the curves which show the relation between the capacity, head, efficiency, and power at a constant speed. These curves are usually obtained from an actual test using water as pumping medium.

\* Published in August, 1928, *Proceedings*.

† Chf. Engr., Pump Div., United Iron Works, Oakland, Calif.

The original ideas which will be presented in this paper occurred to the writer while engaged in research work at the Hydraulic Laboratory of the University of California. These ideas, supplemented by numerous investigations made in the Test Laboratory of the Byron Jackson Pump Manufacturing Company, form the basis for this paper.

#### NOTATION

The following notation has been adopted:

$d_2$  = the diameter at outlet of impeller, in inches.

$b_2$  = the breadth between the impeller disks or shrouds at the diameter,  $d_2$ , in inches.

$z$  = number of vanes.

$A$  = the free exit area at the impeller periphery, in square inches =  $(\pi d_2 - z t) b_2$ .

$D$  = the equivalent diameter of the free area at the impeller periphery  
 $= \sqrt{\frac{4 A}{\pi}}$ , in inches.

$\nu_o$  = kinematic viscosity of oil in poises.

$\nu_w$  = kinematic viscosity of water in poises = 0.01.

$s$  = specific gravity.

$t$  = vane length at periphery (outlet).

$G_o$  = U. S. gallons per minute when pumping oil.

$G_w$  = U. S. gallons per minute when pumping water.

$H_o$  = head, in feet, when pumping oil.

$H_w$  = head, in feet, when pumping water.

$BHP_o$  = brake-horse-power when pumping oil.

$BHP_w$  = brake-horse-power when pumping water.

$HP_f$  = horse-power absorbed to overcome the disk friction.

$x$  = an exponent.

$HP_m$  = horse-power absorbed to overcome journal and stuffing-box friction =  $BHP_w (1 - e_m)$ .

$B$  = distance from the center of a disk to the wall of the casing.

$e_m$  = mechanical efficiency.

$T$  = torque, in foot-pounds.

$e$  = pump efficiency.

$U$  = peripheral velocity of the impeller, in feet per second.

$g$  = gravitational constant = 32.2.

$\theta$  = angle.

$\omega$  = angular velocity.

$n$  = an exponent.

$r$  = radius.

#### GENERAL CONSIDERATIONS

The suitability of a pump for a given service is determined by the characteristic curves. A given pump operating at a constant speed can deliver a

certain quantity of liquid at a given head. As the head is reduced the capacity increases. The maximum value of head occurs near the point of the zero discharge. Theoretically, the maximum head which can be produced by an impeller is,

$$H = \left[ \frac{\text{Diameter, in inches} \times \text{revolutions per minute}}{1840} \right]^2$$

Actually, the maximum head may be more or less than the calculated value, depending mainly on the design of the impeller and of the casing. From given characteristics, new curves can be computed for speeds above and below the operating speed for the same pump. This is possible because if the diameter of the impeller is kept constant:

- 1.—The capacity varies as the first power of the speed;
- 2.—The head varies as the second power of the speed; and,
- 3.—The power varies as the third power of the speed.

It must be emphasized that this is correct if the variation in speed is not very great. Every pump is designed for a certain speed and it will not operate with the same efficiency at a speed very different from that for which it is designed.

Furthermore if the impeller speed is kept constant, provided the width of the impeller is constant:

- (a) The capacity varies approximately as the diameter;
- (b) The head varies as the square of the diameter; and
- (c) The horse-power varies as the cube of the diameter.

These relations are true approximately. Actually, the head drops below the recalculated value. As a rule the efficiency of a pump falls off with the cut, although in some instances when the runner is too large for the casing the efficiency may improve for a relatively small cut.

These laws do not hold near points at which the pump cuts off; that is, points that mark sudden drops of head, efficiency, and horse-power. These drops occur when the suction inlet of the impeller is relatively small and the rate of discharge becomes too great for the net opening area of the impeller and when the pump becomes choked. No matter how wide open the valve on the discharge side of the pump is, the capacity stays constant.

#### DERIVATION OF THE HEAD-CAPACITY EQUATIONS

The effect of pumping different liquids with the same pump, operating at a constant speed, may be stated as follows:

- 1.—The capacity will vary inversely as some power of the kinematic viscosity of the liquid:

$$\frac{G_0}{G_w} = \frac{1}{\left( \frac{\nu_0}{\nu_w} \right)^n} \dots \dots \dots (1)$$

- 2.—The head will vary inversely as the square of the same power of kinematic viscosity of the liquid:

$$\frac{H_0}{H_w} = \frac{1}{\left( \frac{\nu_0}{\nu_w} \right)^{2n}} \dots \dots \dots (2)$$

Hence, the problem is to determine the various factors which affect the exponent,  $n$ .

The writer has found that  $n$  varies directly with the quantity,  $G$ , to some power,  $a$ , and the kinematic viscosity,  $\nu$ , to some power,  $b$ . It varies inversely with the free exit area,  $A$ , to some power,  $c$ . Hence,

$$n = \frac{G_w^a \nu_0^b}{A^c} K \dots \dots \dots (3)$$

Substituting the values:

$$A = (\pi d_2 - z t) b_2 = \frac{\pi D^2}{4} \dots \dots \dots (4)$$

and,

$$K \left( \frac{4}{\pi} \right)^c = K' \dots \dots \dots (5)$$

In Equation (3), the coefficient may then be written,

$$n = \frac{G_w^a \nu_0^b}{D^{2c}} K' \dots \dots \dots (6)$$

This value of  $n$  may then be substituted in Equations (1) and (2), in order to obtain values of  $G_0$  and  $H_0$ .

From experiments, the numerical values of the exponents were found to be:

$$K' = \frac{1}{15}; b = 0.25; \text{ and } 2c = 6 \text{ for } b_2 > \frac{1}{2} \text{ in.}$$

For small values of  $b_2$  the exponent,  $n$ , is very sensitive to any variation in the width of the impeller and it is always better to obtain this dimension by actual measurement. The value of  $2c$  for  $b_2 < \frac{1}{2}$  in. appeared to vary from 6 to 7. For viscosities of 1 600 S.s.u. (Saybolt seconds universal), and higher,  $a = 1.5$ . For viscosities less than this,  $a$  is determined from an empirical equation,

$$a = (\mu \times 0.1055)^{0.08} \dots \dots \dots (7)$$

in which,  $\mu$  is viscosity, in Saybolt seconds universal.

The net result is that Equation (6) becomes,

$$n = \frac{G_w^a \nu_0^{0.25}}{15 D^6} \dots \dots \dots (8)$$

Analyzing Equations (1) and (2), it may be seen that  $\frac{1}{\left(\frac{\nu_0}{\nu_w}\right)^n}$  is ordinarily less than

unity, because  $\frac{\nu_0}{\nu_w}$  for viscous oils is usually greater than 1.

In case  $\frac{\nu_0}{\nu_w} = 1$ , the term,  $\left(\frac{\nu_0}{\nu_w}\right)^n$ , becomes equal to unity,  $G_w = G_0$ , and  $H_w = H_0$ ; that is, when liquids have the same kinematic viscosity, the head capacity curves are the same. On the other hand, the term,  $\left(\frac{\nu_0}{\nu_w}\right)^n$ , may become equal to unity when the exponent,  $n$ , is equal to zero. This is the case when  $G_w = 0$ ; that is, when there is no flow, the "static head" at the shut-off valve is inde-

pendent of viscosity and is approximately equal to  $\frac{U^2}{2g}$ . Since  $U$  is the peripheral speed of the impeller the "static head" depends on the speed of the prime mover and the dimensions of the impeller and is practically independent of the viscosity.

By studying the different factors that influence the exponent,  $n$ , it is possible to improve the design of a centrifugal oil pump. It may be easily noticed that the effect of viscosity on the head-capacity curve decreases rapidly with increases in the size of the pump.

#### DERIVATION OF THE HORSE-POWER EQUATIONS

Consider, next, the horse-power required by a centrifugal oil pump. In general, the horse-power taken by a centrifugal water pump is composed of (1) horse-power to overcome the disk friction; (2) hydraulic horse-power; and, (3) horse-power necessary to overcome the friction in the stuffing-boxes and bearings which, for a uniform speed, is practically constant.

The first two items increase with the viscosity of the liquid, and the brake horse-power of a pump operating in oil, may be expressed in terms of brake horse-power of a water pump by the following formula:

$$BHP_0 = sHPf_w \left( \frac{\nu_0}{\nu_w} \right)^x + (BHP_w - HPf_w - HPM) \left( \frac{\nu_0}{\nu_w} \right)^n s + HPM \dots \dots \dots (9)$$

The factor,  $HPf_w$ , is the horse-power absorbed in overcoming the disk friction in water and is equal to the difference between  $HPf_w$  corresponding to the outlet diameter of the impeller and the  $HPf_w$  corresponding to the inlet diameter of the impeller.

Consider the first term of Equation (9); that is, the disk friction. When an impeller is revolving in a case of a centrifugal pump filled with any liquid, it acts as a brake. (See Fig. 1.) If  $U$  is the velocity of the element at the radius,  $r$ , and  $f$  is a coefficient of friction, the frictional resistance,  $R$ , equals:

$$R = f U^n A \dots \dots \dots (10)$$

or the frictional resistance on an element of the area,  $dA$ ,

$$dR = f U^n dA = f r^n \omega^n (r d\theta dr) \dots \dots \dots (11)$$

The torque necessary to rotate the disk in liquid is,

$$dT = r dR = f r^{n+2} \omega^n d\theta dr \dots \dots \dots (12)$$

$$T = \frac{4\pi f \omega^n}{n+3} r^{n+3} \text{ ft-lb.} \dots \dots \dots (13)$$

Taking into account the thickness,  $b$ ,

$$T^r = 2\pi r b f r^n \omega^n = 2\pi b f r^{n+2} \omega^n \dots \dots \dots (14)$$

$$T'' = T + T^r = 2\pi f \omega^n r^{n+2} \left[ \frac{2r}{n+3} + b \right] \text{ ft-lb.}$$

and,

$$HPf = \frac{T'' \omega}{550} = \frac{2\pi}{550} f \omega^{n+1} r^{n+2} \left[ \frac{2r}{n+3} + b \right] \dots \dots \dots (15)$$

The coefficient,  $f$ , is influenced by the ratio of  $\frac{B}{2r}$ , by the roughness of the surface, the viscosity, and the density of the liquid. Many empirical equations have been published which are a modification of Equation (15), namely, those of Unwin, Lashe, Banki, Gibson and Ryan, Le Conte, V. Zur Nedden, etc.

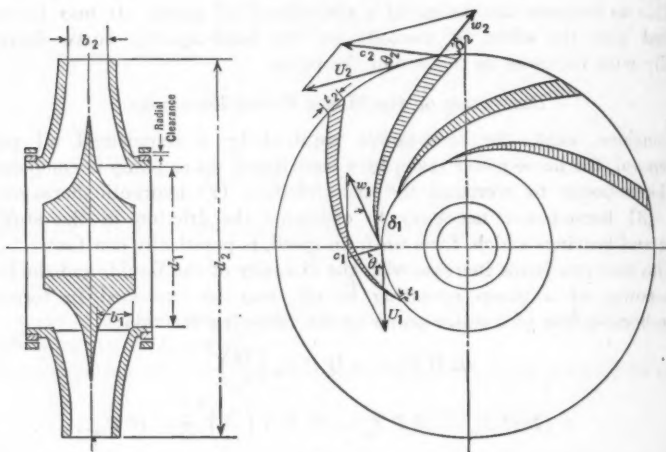

FIG. 1.

Nearly all of them show that the horse-power absorbed to overcome the disk friction varies approximately as the fifth power of the diameter and as the third power of the speed. The writer uses Professor Banki's formula:

$$\text{Horse-power} = \frac{0.0000000961 N^3 d^5}{550}$$

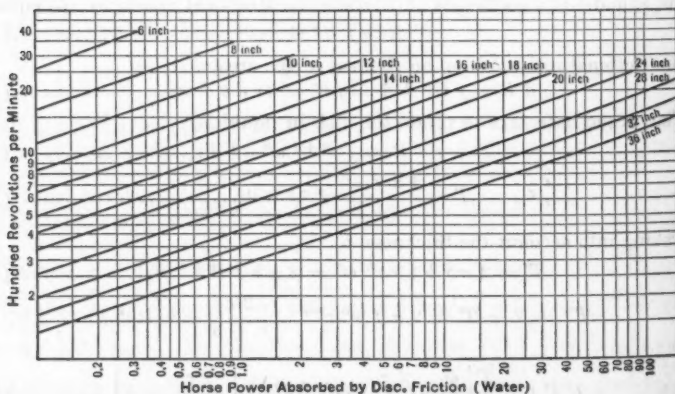

FIG. 2.—FROM PROFESSOR BANKI'S FORMULA FOR DISK FRICTION.

in which,  $N$  = revolutions per minute, and  $d$  = diameter, in feet. This is graphically represented in Fig. 2, which makes it possible to determine the  $HP f_w$  direct for a given speed and diameter of the impeller in a pump with the usual clearances.

If an impeller is revolved at a constant speed in two different liquids, say, first in water and next in a viscous oil, then the relation between horse-power, kinematic viscosity, and specific gravity, is,

$$\frac{HP f_0}{HP f_w} = \left(\frac{\nu_0}{\nu_w}\right)^X \frac{s_0}{s_w} = \left(\frac{\nu_0}{\nu_w}\right)^X s_0 \dots\dots\dots (16)$$

The exponent,  $X$ , is a function of viscosity and is determined for a given viscosity from Fig. 3. This curve was plotted by the writer from experi-

FIG. 3.—VALUES OF  $X$  TO BE USED IN EQUATION (9).

mental data. The second term of Equation (9) is the hydraulic horse-power. It is evident that, due to internal friction, it takes a greater amount of power to move a more viscous fluid and this can be expressed as:

$$HH P_0 = (BHP_w - HP f_w - HP_m) \left(\frac{\nu_0}{\nu_w}\right)^n \dots\dots\dots (17)$$

in which,  $(BHP_w - HP f_w - HP_m)$  is the hydraulic horse-power when pumping water. The exponent,  $n$ , was found to be the same as in Equation (6).

When designing a centrifugal pump it is always important to see that the percentage of horse-power absorbed in order to overcome the disk friction be a reasonable percentage of the total horse-power consumed by the pump. This is especially important when choosing an oil centrifugal pump, because the disk friction constitutes a tremendous loss in such a case, depending on the viscosity of the liquid. The problem of selection, the proper number of stages, dimensions, and angles of an impeller, must be studied very carefully.

In general, for a centrifugal water pump not more than 5% of the total horse-power is allowed for the disk friction. When the required head is high a single-stage pump would require either that the diameter of the runner be large or that the pump be run at a high speed. For this reason a multi-stage pump, with several runners of relatively small diameter, operating in series, is used.

In viscous liquids, the disk friction may be many times greater than in water, and it is always necessary to determine in advance whether a pump which is good for water service is suitable for oil and then select a proper motor.

*Illustrative Example.*—Consider a 5-in. single-stage pump operating at 1750 rev. per min. Let  $d_2 = 10\frac{1}{2}$  in.;  $b_2 = \frac{3}{4}$  in.;  $z = 8$ ; and,  $t = 0.31$  in.

From Equation (4),

$$A = (\pi 10\frac{1}{2} - 8 \times 0.31) \frac{4}{3} = 22.9 \text{ sq. in.}$$

$$D^2 = 22.9 \frac{4}{\pi} = 29.2$$

and,

$$15 D^6 = 373\,000$$

Next, predetermine the characteristics for the pump for oil with a viscosity of 675 S.s.u. and a specific gravity of 0.924. Then the kinematic viscosity in poises is computed by the empirical equation,

$$\nu_0 = \mu \times 0.00216 - \frac{1.8}{\mu} \dots \dots \dots (18)$$

$$\nu_0 = 675 \times 0.00216 - \frac{1.8}{675} = 1.457 \text{ poises}$$

$$\nu_0^{0.25} = 1.1$$

From Equation (7),

$$a = (675 \times 0.1055)^{0.08} = 1.405$$

The computations for the head capacity are shown in Table 1.

TABLE 1.

$G_w$ .	$H_w$ .	$G_w^{1.405}$ .	$n$ .	$\left(\frac{\nu_0}{\nu_w}\right)^n$ .	$\left(\frac{\nu_0}{\nu_w}\right)^{2n}$ .	$G_o$ .	$H_o$ .
880	45.0	18 509	0.0399	1.22	1.49	730	29.5
800	62.5	11 800	0.0349	1.19	1.42	673	44.0
600	85.0	7 760	0.0229	1.13	1.28	531	66.4
500	92.0	6 310	0.0186	1.10	1.21	454	76.0
400	97.0	4 570	0.0135	1.07	1.14	374	85.0
300	100.0	3 020	0.00891	1.06	1.12	283	89.3
200	100.8	1 699	0.00501	1.03	1.06	194	95.0
100	100.1	646	0.00191	1.01	1.02	99	98.0
0	99.0	0	0	1.00	1.00	0	99.0

Next, refigure the horse-power for the same viscosity and specific gravity. When a pump is lifting water, and is operating at full load,

$$BHP_w = 18.3$$

Assuming the mechanical efficiency of the pump to be 97%,

$$HP_m = BHP_w (1 - 0.97) = 0.55 \text{ h.p.}$$

Next, from Fig. 2, the horse-power absorbed to overcome the disk friction in water for an impeller,  $10\frac{1}{2}$  in. in diameter, revolving at 1 750 rev. per min., is:

$$HPf_w = 0.5$$

The  $HPf_w$  for the inlet diameter of the impeller is negligible ( $d_1 = 5$  in.).

From Fig. 3 the exponent,  $X$ , corresponding to a viscosity of 675 S.s.u., is:

$$X = 0.39$$

$$HPf_o = 0.924 \times 0.5 \times 145.7^{0.39} = 3.23$$

TABLE 2.

$G_0$	$BHP_w$	$(H_0)^{1.405}$	$n$	$\left(\frac{v_0}{v_w}\right)^n$	$s(BHP_w - H P f_w - H P_m) \left(\frac{v_0}{v_w}\right)^n$	$BHP_0$
730	20.0	10 500	0.081	1.17	20.5	24.3
673	19.5	9 500	0.028	1.15	19.3	23.1
531	17.5	67 500	0.020	1.105	16.2	20.0

194	11.0	1 180	0.0033	1.017	9.5	13.3
99	9.0	680	0.0019	.....	7.7	11.5

Then tabulate the computations for  $BHP_0$  in the same manner as for the head capacity. (See Table 2.)

Plotting the given values of  $H_0$ ,  $BHP_0$ , and efficiency, against  $G_0$  as abscissa, the oil-pumping characteristics of a centrifugal pump are found as based on water performance. Similar curves were plotted for viscosities of 1350 and 3400 S.s.u. (See Figs. 4, 5, and 6.)

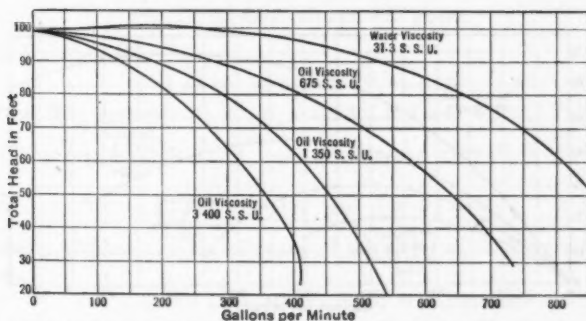

FIG. 4.—HEAD CAPACITY CURVES FOR A 5-INCH SINGLE-STAGE PUMP.

#### PROCEDURE IN COMPUTING THE OIL CHARACTERISTICS OF A MULTI-STAGE PUMP

The case of a multi-stage pump is more complicated than that of a single-stage pump. Oil passing through the first stage, on account of losses, is heated; and the more stages it has to pass, the more pronounced is the heating effect. The heat given to the oil raises its temperature. The change in temperature changes the viscosity, and the drop in head in the first stage will be greater than in the second stage; in the second stage greater than in the third, etc. Therefore, it is necessary, in the case of a multi-stage pump, to calculate the losses in the first stage and express them in British thermal units; determine the increase in temperature; look up the new viscosity corresponding to this temperature; and compute the head-capacity curve for the second stage, basing the calculations on the new viscosity which evidently is

less than that for the first stage. After the head-capacity and brake-horse-power curves are obtained for each stage, it is necessary to add them to obtain characteristics of the entire pump.

This is a very long and tedious task and for ordinary practice it is sufficiently accurate to calculate the head capacity, brake horse-power, and efficiency for a given viscosity for one point, usually at the operating point,

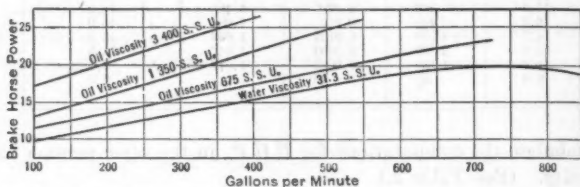

FIG. 5.—BRAKE-HORSE-POWER CURVES FOR A 5-INCH SINGLE-STAGE PUMP.

in the same manner as has been done for a single-stage pump. This will be the first approximation. The next step is to take the difference between the horse-power input in the pump and the horse-power output of the pump, con-

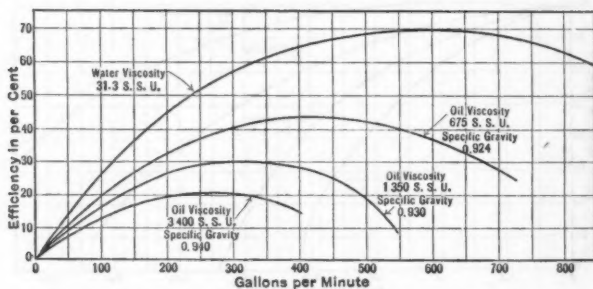

FIG. 6.—EFFICIENCY CURVES FOR A 5-INCH SINGLE-STAGE PUMP.

vert this difference into British thermal units, and knowing the specific heat of the oil (which varies from 0.45 to 0.505), determine the rise in temperature and corresponding viscosity. With the new viscosity determined, the head-capacity, brake horse-power, and efficiency curves for the entire range may be calculated.

*Illustrative Example.*—Consider a four-stage pump operating at 1 750 rev. per min., which has the following dimensions:  $d_2 = 15$  in.;  $b_2 = \frac{1}{2}$  in.,  $t = 0$  in. (vanes filed to a point); and  $z = 6$ .

Then, from Equation (4),

$$A = \pi \times 15 \times \frac{1}{2} = 23.5$$

$$D^2 = 30$$

and,

$$15 D^6 = 405\,000$$

Let the temperature of the oil to be pumped be 104° Fahr. The viscosity corresponding to this temperature equals 1 000 S.s.u. (See Fig. 7.) Then,

$$\nu_0 = 1\,000 \times 0.00216 - \frac{1.8}{1\,000} = 2.16$$

$$\nu_0^{0.25} = 1.21$$

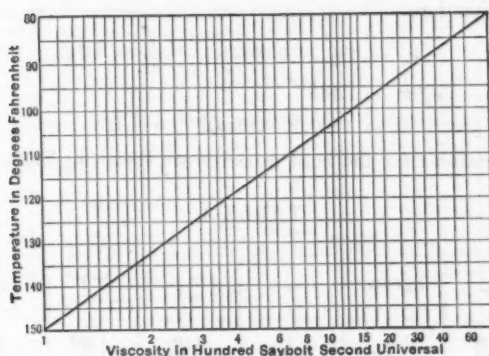

FIG. 7.—VISCOSITY-TEMPERATURE CURVE.

From Equation (7),

$$\alpha = (1\,000 \times 0.1055)^{0.08} = 1.452$$

For the first approximation:  $G_w = 600$ ;  $H_w = 720$ ;  $G_w^{1.452} = 10\,800$ ;

$$n = 0.0387; \left(\frac{\nu_0}{\nu_w}\right)^n = 1.23; \left(\frac{\nu_0}{\nu_w}\right)^{2n} = 1.51; H_0 = 476; G_0 = 487; G_0^{1.452} = 8\,000; n = 0.0239; \left(\frac{\nu_0}{\nu_w}\right)^n = 1.137; \text{ and } BHP_w = 162.$$

Assuming 97% mechanical efficiency of the pump and 0.95 specific gravity of the oil,

$$HP_m = 162 (1 - 0.97) = 4.87 = \text{a constant}$$

$HPf_w$  for an impeller 15 in. in diameter, revolving at 1 750 rev. per min., is 2.75 (from Fig. 2). Therefore, for four stages (neglecting  $HPf_w$  for the inlet diameter),

$$HPf_w = 4 \times 2.75 = 11$$

and the disk friction horse-power, when pumping oil, is found by Equation (16),

$$HPf_0 = 0.95 \times 11 \times 216^{0.402} = 90.2$$

and,

$$BHP_0 = 4.87 + 90.2 + (162 - 11 - 4.87) 0.95 \times 1.137 = 252.7$$

The horse-power lost in heat is equal to,

$$BHP_0 - \frac{G_0 H_0 s}{3\,960} = 252.7 - \frac{487 \times 476 \times 0.95}{3\,960} = 197.2$$

The rise in temperature, in degrees Fahrenheit, is,

$$t_2 - t_1 = \frac{\text{Horse-power lost in heat} \times 42.44}{\text{Specific heat} \times G_0 \times \text{weight}}$$

In this case,

$$t_2 - t_1 = \frac{197.2 \times 42.44}{0.5 \times 487 \times 8.33 \times 0.95} = 4.3^\circ \text{ Fahr.}$$

Hence, the new temperature is  $108.3^\circ \text{ Fahr.}$ , and the corresponding viscosity (from Fig. 7) is 800 S.s.u. Using this viscosity as the basis for the second approximation,

$$\nu_0 = 800 \times 0.00216 - \frac{1.8}{800} = 1.723$$

$$\nu_0^{0.25} = 1.145$$

$$a = (800 \times 0.1055)^{0.08} = 1.425$$

The computations for the head capacity are shown in Table 3.

TABLE 3.

$G_w$	$H_w$	$G_w^{1.425}$	$n$	$\left(\frac{\nu_0}{\nu_w}\right)^n$	$\left(\frac{\nu_0}{\nu_w}\right)^{2n}$	$G_0$	$H_0$
0	830	0	0	1.000	1.000	0	830
200	900	1 900	0.00536	1.028	1.057	195	860
400	845	5 100	0.0144	1.077	1.160	372	728
600	720	9 000	0.0254	1.140	1.300	527	562
800	515	10 850	0.0292	1.160	1.350	690	382

From Fig. 3, the exponent,  $X$ , corresponding to viscosity of 800 S.s.u. is 0.390, therefore,

$$H P f_0 = s \times H P f_w \left(\frac{\nu_0}{\nu_w}\right)^X = 0.95 \times 11 \times 172.3^{0.390} = 77.8$$

The computations for  $B H P_0$  are given in Table 4. All values from Tables 3 and 4 are plotted in Fig. 8, and the characteristics of the pump for oil are obtained.

TABLE 4.

$G_0$	$G_0^{1.425}$	$n$	$\left(\frac{\nu_0}{\nu_w}\right)^n$	$B H P_w$	$H P f_w$	$H P f_0$	$H P_m$	$\frac{s(B H P_w - H P f_w)}{\left(\frac{\nu_0}{\nu_w}\right)^n}$	$B H P_0$
0	0	0	1.000	...	11	77.8	4.87	.....	.....
195	1 850	0.0052	1.027	110	11	77.8	4.87	97.5	180.2
372	4 500	0.0127	1.070	140	11	77.8	4.87	125.8	308.5
527	7 500	0.0212	1.106	170	11	77.8	4.87	161.9	244.6
690	11 000	0.0310	1.175	190	11	77.8	4.87	194.0	276.7

It must be mentioned that the point of cut-off and the lower part of the head-capacity curve, when calculated by the derived equations, may give values which are less than the actual. The reason for this is that the efficiency of the pump decreases toward the cut-off point and at this point practically the whole power is consumed in overcoming losses.

This means that there is a greater heating effect and, consequently, a greater decrease in viscosity at points closer to the cut-off point, and it is evident that the actual head-capacity curve may deviate from the theoretical head capacity which is based on constant viscosity.

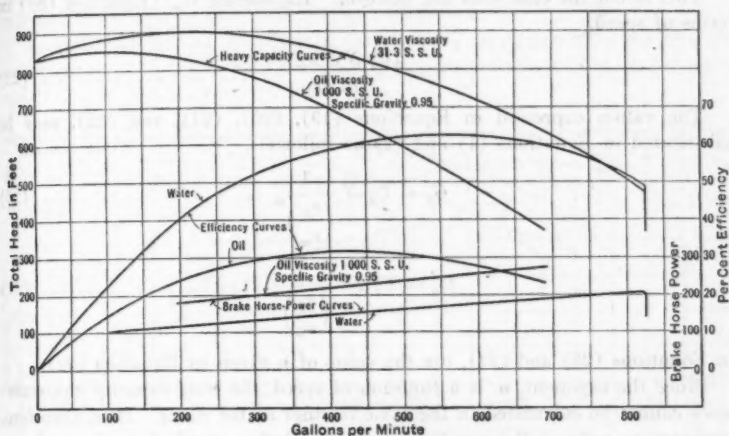

FIG. 8.—CHARACTERISTICS OF 3-INCH, 4-STAGE MULTIPLE PUMP.

Another point which must be emphasized is the effect of leakage. It is well known that the leakage past the runner wear-rings and the casing wear-rings of a centrifugal pump when lifting water is a relatively great loss, particularly for high heads and small pumps. It is evident that the leakage decreases with the viscosity, resulting in an increase of the volumetric efficiency of the pump. This probably is the reason for the increase of the exponent,  $c$ , for pumps of small sizes.

#### CALCULATION OF THE OIL CHARACTERISTICS FOR DIFFERENT SPEEDS

Suppose a pump had been tested at two speeds with oil and the performance from oil to oil was refigured for each speed. How do these oil performances for two different speeds compare? In other words, is it correct to refigure from a given performance of a pump on oil at one speed to another speed in the same way as is done for water?

Since in case of water the head varies as the square of the speed and the capacity as the first power of speed,

$$H_w = C_1 N^2 \dots \dots \dots (19)$$

$$G_w = C_2 N \dots \dots \dots (20)$$

and,

$$H_w = C G_w^2 \dots \dots \dots (21)$$

In Equations (19), (20), and (21),  $N$  is the speed, in revolutions per minute, and  $C$  is a constant, for a given point, and is determinable for a given pump from the head-capacity curve at a given speed. Hence, if the speed is doubled,

the capacity is also doubled, and the head is increased four times. In other words, when the pump is operated in water the reduction of a point at different speeds follows a line of relatively constant efficiency. This is a straight line with a slope of 2:1 when plotted on logarithmic paper.

This is not the case with oil, however. Expressing  $G_w$  (Equation (8)) in terms of speed,

$$n = \frac{(C_2 N)^a \nu_w^{0.25}}{15 D^6} \dots \dots \dots (22)$$

The values expressed in Equations (19), (20), (21), and (22), may be substituted in Equations (1) and (2) as follows:

$$G_0 = C_2 N \frac{1}{\left(\frac{\nu_0}{\nu_w}\right)^n} \dots \dots \dots (23)$$

$$H_0 = C_1 N^2 \frac{1}{\left(\frac{\nu_0}{\nu_w}\right)^n} \dots \dots \dots (24)$$

In Equations (23) and (24), use the value of  $n$  given in Equation (22).

Since the exponent,  $n$ , is a function of speed, the head-capacity characteristics cannot be calculated in the same manner as for water. It is, therefore, necessary to refigure the speeds for water and then recalculate the performance from water to oil as shown. The same result will be obtained if the constants,  $C_1$  and  $C_2$ , are determined from Equations (19) and (20) and the values of these constants and the speed,  $N$ , are substituted in Equations (23) and (24).

*Illustrative Example.*—Consider the 5-in. double-suction, single-stage pump which was used in Example 1 and calculate the characteristics for 1 450 rev. per min.

From Table 1,

$$G_w = 800; H_w = 62.5 \text{ at } 1\,750 \text{ rev. per min.}$$

From Equations (19) and (20),

$$C_2 = \frac{800}{1\,750} = 0.457$$

$$C_1 = \frac{62.5}{1\,750^2} = 0.0000205$$

By Equation (22),

$$n = \frac{(0.457 \times 1\,450)^{1.405} \times 1.1}{373\,000} = 0.02714$$

Substituting these values in Equations (23) and (24) and assuming that  $N = 1\,450$  rev. per min.,

$$G_0 = 0.457 \times 1\,450 \frac{1}{(145.7)^{0.02714}}$$

$$G_0 = 577$$

$$H_0 = 0.0000205 \times 1450^2 \frac{1}{(145.7)^2 \times 0.02714}$$

$$H_0 = 32.7$$

In like fashion all the points can be determined and a smooth head-capacity curve can be passed through these points.

As an illustration of the effect of the viscosity on pumps of larger size, the performance of a 10-in. double-suction pump is plotted in Fig. 9 for water and for oil with a viscosity of 1200 S.s.u.

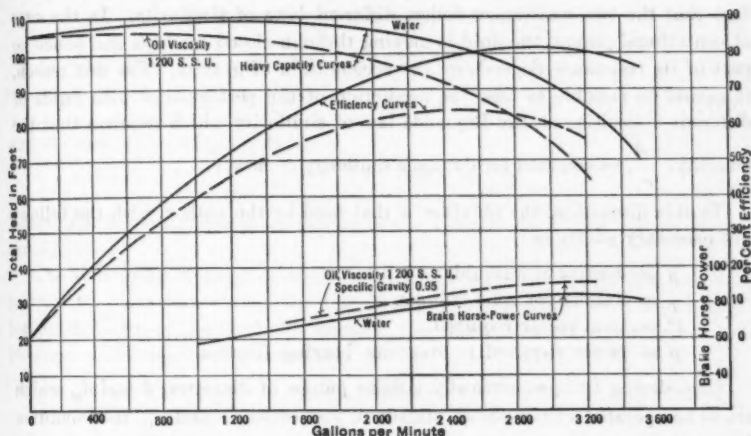

FIG. 9.—CHARACTERISTICS OF 10-INCH DOUBLE-SUCTION PUMP.

### CONCLUSIONS

From these considerations, the following conclusions may be made:

- 1.—It is possible to predetermine, with a sufficient degree of accuracy, the performance of a centrifugal oil pump by observing its characteristics as obtained on water.
- 2.—The effect of the viscosity is to decrease the head capacity and increase the power.
- 3.—When the pump is working in viscous oil, the increase in horse-power is influenced mainly by the increase in the disk friction due to viscosity.
- 4.—The head-capacity characteristic and the efficiency of a centrifugal pump as applied to viscous oils improve with the increase of the size of the pump.
- 5.—The volumetric efficiency, particularly that of a low specific speed centrifugal pump, improves with the increase of the viscosity.
- 6.—In a multi-stage pump the performance is improved because of the heating of the oil in the pump by losses. This is more noticeable in pumps of low specific speed.
- 7.—It seems that an impeller with "flat" characteristics will be more efficient when pumping viscous oils than an impeller with "steep" characteristics.

## DISCUSSION

MORROUGH P. O'BRIEN,\* ASSOC. M. AM. SOC. C. E. (by letter).—The author's method of predicting the characteristics of an oil pump from its behavior when pumping water is somewhat similar to the method used in predicting the total resistance of a ship from tests of a geometrically similar model. The skin friction and the residual wave and eddy resistance are separated and stepped up to the full scale in different ratios, a procedure that is made necessary by the fact that the two resistances follow different laws of similarity. In the case of centrifugal pumps, the fluid is moving through closed conduits and hence no part of its resistance depends on the acceleration of gravity. For this reason, it should be possible to base the prediction of the performance with fluids of different viscosities on the Reynolds law of similarity which requires that the quantity,  $\frac{v d}{\nu}$ , be constant for dynamic similarity of flow.†

In this discussion, the notation is that used by the author, with the following necessary additions:

$\rho$  = density of a liquid.

$\gamma$  = weight per unit volume.

$P$  = total power required.

$p$  = power required to overcome bearing friction.

Considering two geometrically similar pumps of diameter,  $d$  and  $d_0$ , which are to be operated with fluids of kinematic viscosities,  $\nu$  and  $\nu_0$ , the condition for similarity is:

$$\frac{U d}{\nu} = \frac{U_0 d_0}{\nu_0} \dots \dots \dots (25)$$

in which,  $U$  and  $U_0$  are the velocities at the points to which  $d$  is measured. Substituting for the velocities in terms of the quantity flowing and the areas,

$$\frac{G d}{A \nu} = \frac{G_0 d_0}{A_0 \nu_0} \dots \dots \dots (26)$$

Since the two pumps are geometrically similar, the areas are proportional to the squares of the diameters and,

$$\frac{G}{G_0} = \frac{d \nu}{d_0 \nu_0} \dots \dots \dots (26)$$

To obtain the relation between the speeds of rotation, the velocity,  $U$ , is replaced in Equation (25) by the angular velocity,  $\omega$ , and the diameter,  $d$ , with the result that:

$$\omega = \omega_0 \left( \frac{d_0}{d} \right)^2 \frac{\nu}{\nu_0} \dots \dots \dots (27)$$

\* Asst. Prof. of Mech. Eng., Univ. of California, Berkeley, Calif.

† "Die Grundlagen der Aehnlichkeits Mechanik und ihre Verwertung," Weber, Jahrbuch der Schiffbautechnischen Gesellschaft, 1919.

To determine the corresponding heads, the various components of the total head must be considered. For the pressure head, or head due to centrifugal action,

$$\frac{H'}{H_0'} = \frac{\rho \omega^2 d^2 \gamma_0}{\rho_0 \omega_0^2 d_0^2 \gamma}$$

in which,  $H'$  is the pressure head of the liquid, in feet;  $\rho$  is the density of the liquid; and  $\gamma$  is the weight per unit volume. Considering geometrically similar volumes,  $V$  and  $V_0$ , similarly placed in the two pumps, the kinetic energy is:

$$K E = V \rho \frac{v^2}{2}, \text{ and } K E_0 = V_0 \rho_0 \frac{v_0^2}{2} \dots \dots \dots (28)$$

the velocity heads, or kinetic energy per unit weight, are,

$$H'' = \frac{V \rho v^2}{2 V \gamma}, \text{ and } H_0'' = \frac{V_0 \rho_0 v_0^2}{2 V_0 \gamma_0} \dots \dots \dots (29)$$

and the ratio of velocity heads is,

$$\frac{H''}{H_0''} = \frac{\rho v^2 \gamma_0}{\rho_0 v_0^2 \gamma} = \frac{\rho \omega^2 d^2 \gamma_0}{\rho_0 \omega_0^2 d_0^2 \gamma} \dots \dots \dots (30)$$

Losses due to impact are proportional to the velocity head, and will be in the same ratio.

The remaining element of the total head to be considered is the loss due to friction. Experiments on the flow of fluids in pipe lines have shown that for equal values of the Reynolds number, the values of the friction factor are identical. This may be expressed as:

$$\frac{R}{\rho v^2} = \frac{R_0}{\rho_0 v_0^2} \dots \dots \dots (31)$$

in which,  $R$  is the force per unit area resisting the motion. The resistance per unit area is proportional to the product of the loss of head, due to friction,  $H'''$ , and the unit weight. Substituting this relation:

$$\frac{H'''}{H_0'''} = \frac{\rho v^2 \gamma}{\rho_0 v_0^2 \gamma_0} \dots \dots \dots (32)$$

or,

$$\frac{H'''}{H_0'''} = \frac{\rho \omega^2 d^2 \gamma_0}{\rho_0 \omega_0^2 d_0^2 \gamma} \dots \dots \dots (33)$$

It appears that all the elements of the total head are in the same ratio for dynamically similar conditions.

To test this method, the rotational speeds of the two geometrically similar pumps should be in the relation given by Equation (27). The heads should then be adjusted, until the quantities are in the ratio given by Equation (26). If the Reynolds law of similarity is true, the observed heads should then be in the ratio,

$$\frac{H}{H_0} = \frac{\rho \omega^2 d^2 \gamma_0}{\rho_0 \omega_0^2 d_0^2 \gamma} \dots \dots \dots (34)$$

The relation between the total power,  $P$ , required is,

$$\frac{P - p}{P_0 - p} = \frac{\gamma^3 \rho d_0}{\gamma_0^3 \rho_0 d} \dots \dots \dots (35)$$

in which,  $p$  is the power required to overcome bearing friction.

It should be noted that the geometric similarity of the two pumps should extend also to the surface roughness, which is a difficult condition to fulfill. For the purpose of checking this law of similarity, the impellers and casings might be given an artificial roughness proportional to the diameters. If the scale ratio is small, a rough agreement should be obtained by making both pumps of the same material.

If the scale ratio is unity, corresponding to the use of the same pump for both liquids, the speed ratio becomes,

$$\frac{\omega}{\omega_0} = \frac{v}{v_0} \dots \dots \dots (36)$$

Should it be desirable to use the same speed of rotation, the diameters must be in the ratio,

$$\frac{d}{d_0} = \sqrt{\frac{v}{v_0}} \dots \dots \dots (37)$$

The ratio of the kinematic viscosity of some common oils to that of water is about 18, making the fulfillment of Equation (36) difficult unless special testing equipment is used.

The author's method does not appear to be based on the condition of dynamic similarity of flow and, for this reason, it is applicable only in the range of types, diameters, and viscosities for which the coefficients have been determined. However, the method possesses the very definite advantage of simple experimental procedure. Unfortunately, the paper does not contain a comparison of the oil-pumping characteristics as predicted from water characteristics, and the actual oil-pumping characteristics as obtained by experiment.

MICHAEL D. AISENSTEIN,\* ESQ. (by letter).—The writer agrees with Professor O'Brien's desire to use the Reynolds' law of similarity, which requires that the quantity,  $\frac{v d}{\nu}$ , be constant for dynamic similarity of flow; but several factors that make the application of Reynolds' criterion rather difficult should not be overlooked.

*Argument No. 1.*—Consider the various components of the total head:

$$H = h_w + h_{fw} + h_{sw} \dots \dots \dots (38)$$

in which,

$H$  = total theoretical head for finite number of vanes.

$h$  = total head.

$h_f$  = friction head.

$h_s$  = loss in head due to sudden enlargement.

The subscripts,  $w$ , and  $o$ , denote water and oil, respectively.

If the flow throughout the pump is turbulent, the relative nature of the liquids pumped is immaterial theoretically and:

$$h_w + h_{fw} + h_{sw} = h_o + h_{fo} + h_{so} \dots \dots \dots (39)$$

\* Chf. Engr., Pump Div., United Iron Works, Oakland, Calif.

Assuming for simplicity that the "shock loss" is not affected by viscosity,

$$h_{sw} = h_{s0}$$

and,

$$h_0 = h_w + h_{fw} - h_{f0} \dots \dots \dots (40)$$

In general, loss in head due to friction for a steady flow in straight circular pipes is given by the formula:

$$h_f = K L d^{n-3} v^n \nu^{2-n} \dots \dots \dots (41)$$

and for two different liquids when the flow is turbulent,

$$\frac{h_{fw}}{h_{f0}} = \frac{v_w^n \nu_w^{2-n}}{v_0^n \nu_0^{2-n}}$$

Since  $v$  is a function of  $G$ :

$$\frac{h_{fw}}{h_{f0}} = \frac{G_w^n \nu_w^{2-n}}{G_0^n \nu_0^{2-n}} \dots \dots \dots (42)$$

Substituting the value of  $h_{f0}$  from Equation (42) in Equation (40):

$$h_0 = h_w + h_{fw} \left( 1 - \frac{G_0^n \nu_0^{2-n}}{G_w^n \nu_w^{2-n}} \right) \dots \dots \dots (43)$$

Experiments\* indicate that for a curved rotating channel, the critical velocity is not proportional to the value of the coefficient of viscosity; that is,

its value does not conform to the theoretical condition that  $\frac{v d}{\nu}$  is constant.

Moreover, to solve Equation (43), it is necessary to know the laws of frictional resistance for revolving channels in liquids of different viscosity and the effect of viscosity on sudden enlargement losses. As far as the writer knows, this information is not available at present.

*Argument No. 2.*—In the model of a pump, the dimensions of which are truly proportional to the original,  $G$  is proportional to  $u b d$ , when  $u$  is the peripheral velocity,  $d$  is the diameter of the impeller, and  $b$  is the width of the impeller.

Since, when  $N$  equals revolutions per minute,

$$u = \frac{\pi d N}{60} \dots \dots \dots (44)$$

and  $b$  is proportional to  $N b d^2$ . In the same manner,  $h$  is proportional to  $N^2 d^2$ .

For two geometrically similar pumps:

$$\frac{G_1}{G_2} = \frac{N_1 d_1^2 b_1}{N_2 d_2^2 b_2} \dots \dots \dots (45)$$

and,

$$\frac{h_1}{h_2} = \frac{N_1^2 d_1^2}{N_2^2 d_2^2} \dots \dots \dots (46)$$

If the ratio of all the linear dimensions between the given pumps is  $M$ , then from Equations (45) and (46):

$$G_1 = G_2 M^3 \frac{N_1}{N_2} \dots \dots \dots (47)$$

$$h_1 = h_2 M^2 \frac{N_1^2}{N_2^2} \dots \dots \dots (48)$$

\* Staunton, "Friction".

and (correspondingly),

$$BHP_1 = BHP_2 M^5 \frac{N_1^3}{N_2^3} \dots \dots \dots (49)$$

These equations based on dynamic similarity are found to be approximately correct.

For instance with ratios of 1:2, the specific speed of pumps changed 7%, although theoretically to satisfy the dynamic similarity the specific speed should have been constant.

The viscosities of oils being moved by centrifugal pumps reach a value of 6 000 S. s. u. (Saybolt seconds universal) for larger pumps and values as high as 3 000 S. s. u. are very common.

With corresponding ratio of kinematic viscosities of approximately,

$$\frac{\nu_0}{\nu_w} = 1\ 295 \text{ and } 648$$

For  $\frac{\nu_0}{\nu_w} = 18$ , which was given by Professor O'Brien as most common in practice, the head capacity is practically the same for oil and water for pumps 3 in. in size and greater. The only change which takes place is in horse-power which increases slightly due to increased disk friction, depending on the diameter of the impeller and the operating speed. Consequently, little new information would be gained by testing pumps within the range of viscosities mentioned by Professor O'Brien.

For higher values of viscosities the method of testing pumps suggested by Professor O'Brien does not seem to be practicable, because of the "scale effect" and due to reasons outlined in Argument No. 1.

Professor O'Brien asks how the oil-pumping characteristics predicted from water characteristics given in the paper compare with the actual oil-pumping characteristics, as obtained by experiment. The agreement with the actual tests was very close.

Paper No. 1735

COUNTY SEWER DISTRICT WORK IN OHIO AND  
ASSESSMENT OF COST ACCORDING TO  
BENEFITS\*

By E. G. BRADBURY,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. O. BONNEY, R. F. MACDOWELL, F. D. STEWART,  
W. M. OLSON, FRANK C. TOLLES, AND E. G. BRADBURY.

SYNOPSIS

Under Ohio laws, county sewer districts may be created and sewers and water mains may be constructed therein, the cost being defrayed by assessments levied on property benefited. More than 2000 miles of construction have been executed under these provisions, largely in suburban or rural areas.

The character of the territory served involves special problems of design both as to boundaries of districts and provision for future development. The writer's basis of estimating proper sewer and water main capacities is described.

In the plan for the apportionment of assessments for trunk sewers in districts only partly sewered, the fundamental basis is the enhancement of value of the property affected, by reason of the improvement. The actual effect on market price cannot be predicted with accuracy, but a theoretical enhancement is worked out. The factors used are:

- 1.—The future cost to any part of the district for additional trunk or main sewers, for which a present credit is allowed.
- 2.—The estimated period in the future when service will be given to each part of the district, and an adjustment on present worth basis.
- 3.—The relative value of the land, a factor being used proportionate to the square roots of appraised values.

\* Presented at the meeting of the Sanitary Engineering Division, Columbus, Ohio, October 13, 1927.

† County San. Engr., Columbus, Ohio.

Similar methods are used in case of storm sewers and water mains, subject to special considerations due to the character of each.

#### HISTORY OF LEGISLATION

For a number of years the County Sewer District Law of Ohio has been a unique piece of legislation. Until recently, if the writer is correctly informed, it has represented the only attempt to provide for sewer and water facilities in unincorporated suburban and rural communities by laws of general application. One or two other States, however, now (1927) have laws of somewhat similar character.

This law is not to be confused with the "Sanitary District Act of Ohio," which authorizes the creation by the Court of Common Pleas of Sanitary Districts, including two or more political subdivisions, and the construction therein of main sewerage and water supply works for the service of the several units of such District, as the latter Act is designed for the service of contiguous or near-by municipalities, and makes no provision for local service.

The Ohio County Sewer District Law\* dates back to 1911, when a crude and insufficient enactment sought to provide for the creation of county sewer districts and the construction of sewers therein. This law was soon found to be faulty and was amended in 1913 to a workable form. Some years later, further sections were added, authorizing the construction of water supplies in sewer districts and additional amendments have been passed from time to time.

An apparently radical defect in these laws, in that they did not provide for proper notice and hearings prior to the construction of improvements, was developed by litigation in Logan and Trumbull Counties within the past two years, the Courts in both cases indicating doubt as to the propriety of this procedure although failing actually to deny the constitutionality of the sections criticized. Amendments passed by the last session of the General Assembly provide in detail for such notice and hearings and the statute is now believed to be sound.

#### THE EXISTING LAW

As the law now stands, power is given to the county commissioners of any county to create, by resolution, sewer districts outside of municipalities, and to construct therein sewers, sewage treatment works, water supplies, and water mains, assessing the whole, or a part, of the cost on the property benefited. By authority of the council of any city or village, a part, or the whole, of such municipality may be included as a part, or the whole, of a county sewer district. Provision is made for joint construction and maintenance by two or more political subdivisions. The construction of utilities of this class by private interests, without the approval of the county authorities, is forbidden. The appointment of an engineer and assistants is provided for.

\* Comprised in Sections 6602-1 to 6602-33 of the Revised Statutes of Ohio.

The details of procedure are described at considerable length. A general plan of sewerage or water supply for the entire area is the first requirement after the creation of a district. Then follow detailed plans, specifications, estimates, and tentative assessments for such parts as it may be necessary to construct, a resolution of necessity, notices, public hearing, ratification or amendment, and the resolution to proceed. Provision is made for the issuance of bonds or certificates of indebtedness and the levying of revised assessments based on actual cost, but substantially in the same proportion as the tentative assessment.

#### RESULTING SANITARY DEVELOPMENT

Twenty-six of the eighty-eight counties of Ohio have acted under this law, in its various forms, and the extent and value of the work have far exceeded expectations. In an effort to secure full information, a letter of inquiry was mailed to the Sanitary Engineer of each of these counties. In the twelve counties from which replies were received there have been created seventy-nine sewer districts, with a total area of 336 600 acres. In these districts, sewers constructed or under construction total 807 miles, and water mains, 797 miles. Fifteen sewage disposal plants and six water supplies are reported in the same counties. Data from the remaining counties are not available, but it is very conservative to assume that more than 2 000 miles of sewers and water mains have been built under this procedure within the State.

Most of the work is the extension of the sewer and water systems of the larger municipalities, although quite a number of summer resorts and small rural communities have been provided with independent systems. The possibility of competent and systematic control of these matters in suburban areas is of great advantage to the cities, as inadequate design and improper construction are avoided, development is encouraged, and utilities are constructed at the entire expense of the property benefited. The city, of course, must be compensated for services in transporting and disposing of sewage and for water furnished.

In some of the counties, a city annexing territory that has been improved under this law simply takes over the sewers and water mains therein without compensation, and continues their operation. In others, a plan has been developed by which the city pays present value of these improvements when annexations are made. This is a question to be studied in each case, as the proper solution depends on how the city finances its own work of the same character. It is often a complex and many-sided problem.

The collection of interest on deferred installments of assessments at a rate equal to that on bonds sold to meet cost of construction, and a provision of the law that maintenance assessments may be levied as necessary, make possible the operation of sewer and water systems for rural communities much smaller than can be provided for by any other method. One water supply in Franklin County, consisting of a deep well, pumps, an elevated tank, and a distribution system, was operated for several months with twelve service taps and has never had more than seventy-five customers, yet water is sold at 35 cents per 1 000 gal., plus a service charge of 50 cents per month, and after

four years of operation the original maintenance fund is intact and a small surplus has been accumulated. This is possible because there is no interest charge included in the water rates and a large replacement fund need not be built up, as future contingencies can be met when they arise by further assessment. This project was installed at a cost to the property owners of about \$100 per lot.

#### EXTENT OF DISTRICTS AND SEWAGE FLOW

The determination of the proper boundaries of a sewer district presents a rather difficult problem. Correct sewer design requires that provision be made for many years in the future, and, within the time designed for, the natural growth of the community will cover much land which is now used only for agricultural purposes, although usually valued at speculative prices. Often such territory, if not included, can not be later sewered except at great expense. Many owners resent even a small present assessment, and demand that their property be omitted. When such objection becomes general over an outlying part of a district, and cannot be satisfied by explanation, it is impossible to proceed against it, and a more short-sighted policy must be adopted.

In many of the districts there is much entirely undeveloped territory. This condition renders design somewhat difficult, because of the problematical character of future development. It is reasonable to expect such areas to become very largely residential in character, although more or less industrial activity will probably follow railroad lines; ordinarily, commercial development will be limited to small local trading centers. In Franklin County the practice is to design for residential purposes only, using figures sufficiently liberal to take care of any reasonably probable manufactural or commercial demand.

The basis of sewer design used by the writer differs somewhat from the ordinary standards. It recognizes the probability that there may be a congestion of population in any given part of the district and the possibility that this may occur anywhere in the district, but is not likely to extend over large areas. It provides for a wider variation between average and maximum flows in small areas than in large; and it anticipates a greater ground-water infiltration than is assumed by many engineers. Although using the most careful methods of construction, the writer has never been able to prevent material increases of flow during wet periods, due to infiltration through joints and manholes, admission of surface water through manhole tops, leakage of house connections, and doubtless some water from roofs or surface water inlets surreptitiously connected. It is of some interest to note that, with manholes 300 ft. apart, an average of one leak in each manhole equivalent to a  $\frac{1}{4}$ -in. orifice under 2-ft. head, will amount to about 25 000 gal. daily per mile, or 750 gal. daily per acre. An average of 2 drops per sec. from each joint of a pipe sewer will total about the same figures. That is, if the leakage is to be kept down to 750 gal. per acre, the infiltration for each 300 ft. of sewer must not exceed one  $\frac{1}{4}$ -in. leak, or a somewhat rapid dripping from each joint.

On the other hand, the average domestic consumption in Columbus is about 50 gal. per capita daily, or approximately 50% of the average per capita use

for all purposes. This figure is accurately verified by the use of water in residential suburbs controlled by master meters.

#### BASIS OF DESIGN

In view of these considerations the following basis of sewer design has been established: (1) The future population is estimated according to a curve ranging from 40 people per acre for areas of 100 acres or less to 20 people per acre for areas of 500 acres or more; (2) it is assumed that the domestic sewage will average 75 gal. per capita daily; (3) that the maximum domestic flow will vary along a curve from 300% of the average in areas of 100 acres or less to 225% in areas of 1 000 acres or more; and (4) for ground-water infiltration, a flat rate of 3 000 gal. per acre daily is assumed. The net result of these figures is as follows:

Acres.	Cubic feet per second per acre.
50 or less .....	0.020
51 to 100 .....	0.019
101 to 125 .....	0.018
126 to 150 .....	0.017
151 to 175 .....	0.016
176 to 200 .....	0.015
201 to 250 .....	0.014
251 to 300 .....	0.013
301 to 400 .....	0.012
401 to 500 .....	0.011
501 or more .....	0.010

In applying this tabulation quantities corresponding to the total area contributing are used and not a cumulative total. It will be noted that larger capacities are provided for small areas than are advocated by many engineers. This seems desirable in view of the fact that overtaxed sewers are much more frequently found near the upper end of a system than in the intercepting or outfall sewers. In the larger areas the capacity is approximately equal to 320 gal. per capita daily for a population of 20 per acre.

In designing general water systems the same uncertainty as to the future exists, and the engineer must avoid the extremes of hopeless inadequacy and dangerous optimism. Such a layout as will doubtless ultimately be required would involve capacities greater than are likely to be needed for many years, with consequent unduly heavy present assessments; it is also necessary to avoid the danger of insufficiency of service in too short a period. The possibility of future reinforcing mains and the character of the fire risk are taken into consideration in the Franklin County Department, and the general rule is to design for 20 people per acre, using an average of 50 gal. per capita, with a maximum of 225% of the average, plus a fire provision equal to three fire streams for the first 500 acres, plus one stream for each additional 500 acres. In view of the residential character of the expected development, this should provide satisfactory service for a reasonable period of gradual growth. In case of greater demand, supplementary mains will have to be constructed later.

## ASSESSMENTS

Perhaps the most interesting feature of the work is the apportionment of assessments for trunk sewers and the larger water mains. The law provides that, where such works are constructed, the abutting property shall be assessed for local service, and the excess cost, less such part as may be paid by the county at large, shall be assessed over the entire area benefited, including the abutting property, as a district assessment divided in proportion to benefits.

The first question arising from this provision is as to the amount, if any, that should be paid by the county, and included in general taxes. In municipal work, it is frequently provided by law that some part of sewer and water systems be financed by such taxes levied over the entire city. J. L. Van Ornum, M. Am. Soc. C. E.,\* found that 19 out of 50 cities investigated paid the cost of main sewers by general taxation, and that 6 more paid the cost less a local assessment on abutting property. He states that this is proper in view of the general benefit to the community due to the establishment of a proper sewer system. In a report to the Sewerage Commissioners of Brockton, Mass., published in 1894, F. Herbert Snow, M. Am. Soc. C. E., stated that the Massachusetts law required that from one-fourth to two-thirds of the cost of common sewers should be paid from tax levies, and that, in his judgment, in the case of a separate system, one-fourth of the total cost of the system fairly represented the share of benefit accruing to the city as a whole.

There is, however, an essential difference between municipal and county conditions, in that all parts of a city may reasonably be expected to require sewers and water mains, either at once or in the very near future, while counties include, as a rule, large areas of agricultural land so remote from any city as to remove any possibility of urban development for generations. A general county tax must include these farm lands and, except in rare cases and under very unusual conditions, the payment of any part of the cost of this work by such taxation is unjust and cannot be considered. If the law permitted the levying of a tax within the limits of a sewer district, it would be a very different matter, but as this is not the case and since it is necessary to consider each sewer district as a separate body politic in designing and financing these improvements, the cost of each system must be defrayed by the assessment method.

When the law, as in this case, requires apportionment in proportion to benefits, it is almost universally held that the judgment of the assessing board will not be disturbed by the Courts unless fraud is shown or confiscatory assessments levied. This principle, together with other rules affecting assessments, has been very clearly stated in a recent Ohio decision.†

## ASSESSMENT PROPORTIONAL TO ENHANCEMENT

The writer is of the opinion that enhancement of value is the proper and logical, as well as the legal, measure of benefit, and that the use made of the property at the time should not be considered, except as it may affect the major question. An assessment once levied cannot be changed, and, if he

\* "Theory and Practice of Special Assessments," *Transactions*, Am. Soc. C. E., Vol. XXXVIII (1897), p. 336.

† *Rogers vs. Johnson, Treas.*, 21 Ohio App. May 7, 1926, Mauck, P. J.

chooses, the owner of vacant land may construct buildings soon after the assessment is levied, that will make greater use of the sewer than those previously built by his neighbors. Failure of any owner to utilize his land should not relieve him of his proper charge. These principles are supported by the best legal authorities and by numerous Courts.\*

The enhancement basis being adopted, it is evident that the character and value of the land become factors in estimating benefit. It has been held by the Courts that either valuation or area, or both, may constitute a proper basis for such apportionment. Mr. Snow gives an illustration showing that the valuation basis, if used in direct proportion, must work a hardship on the more valuable property, but it may be safely assumed that land worth \$2 000 per acre must appreciate in value (expressed in dollars per acre) to a greater extent than \$200 land, when furnished with sewer and water facilities. Assuming that the cost of these improvements was equal to an average of \$200 per acre, it cannot be true that the one is benefited only 10%, while the other is doubled in value. The fact doubtless lies somewhere between the two extremes and after much consideration the writer has reached the conclusion that if, in connection with the other factors later described, the assessment is apportioned in the ratio of the square root of the values, substantial justice will be done. This brings about a result approximately equivalent to spreading one-half the assessment in the ratio of value and one-half on a direct area basis. Land values only are considered, as the buildings are under control of the owner and may be entirely changed at any time.

It is admittedly impossible to determine the precise effect of any public improvement on the market value of property in the district. All that can be done is to estimate what should be the effect. All authorities agree that it is impossible to apportion an assessment with absolute accuracy and correctness, but an effort should be made to establish a method which will result in substantial equity.

As far as the writer has been able to learn, no attempt has ever been made to analyze this problem, although Professor Van Ornum refers to a case in which various factors were considered, but without explaining the method used. Many engineers have adopted a more or less arbitrary plan of establishing zones at varying distances from the improvement and fixing percentages representing the relation of the rates in such zones. In many cases, the assessment is apportioned simply in accordance with the personal judgment of the officials as to relative benefits. The plan originated by the writer, which is used in Franklin County, and has been adopted by several other counties in Ohio, represents an effort to establish a fair and equitable basis and, as it is believed to present some new ideas, will be described in detail.

#### METHOD OF APPORTIONMENT

The plan is based on the following premises:

- 1.—The measure of benefit is the difference in value of the property before and after the improvement is made.

\*City of Butte 2. School Dist. No. 1, 29 Mont. 336 339, 74 Pac. 869 (1904). See, also, "Taxation by Special Assessments," by Page and Jones; "Law of Special Assessments," by Hamilton; and "Municipal Corporations," by McQuillan.

2.—Valuable land is benefited more than cheap land, although not in proportion to the ratio of the values, the square root of the value ratio being assumed to represent this item fairly.

3.—The present use of the land, or the presence or absence of buildings is not ordinarily a factor, being subject to radical change and wholly under control of the owner.

4.—In the case of a district completely sewered at one operation, the cost of trunk sewers and disposal facilities could fairly be assessed over the district on an area basis, subject only to the valuation correction, and such an apportionment should represent a reasonable estimate of the enhancement of value.

5.—When only the main works of the system are built, designed to serve the whole district ultimately, the assessment should be so adjusted that when the system is completed, each property in the district will have been assessed equally per unit of area, as of the date when service is given, subject to correction for valuation.

6.—Following the thought of Premise 5, it is evident that property which will later be assessed for a share of main sewer extensions or branch mains, is correspondingly less benefited by the sewer now built than property which will not require such an extension or branch. This feature of the problem may be called "accessibility".

7.—It is equally clear that property which is not given immediate service is less benefited than that which has such service, and that a fair measure of this factor, which may be called "time", is the ratio of the present worth of a dollar, for a period equal to the probable time which will elapse before service is rendered, to the basic dollar.

In order to develop such a distribution of the district assessment it is necessary to estimate the cost of future extensions and branch mains, the period at which each portion of the district will be so developed as to require sewerage, and the value of the land. The first is a simple matter of estimating costs from the general plan. The second is obtained by dividing the district map into rather small zones, calling in the services of several qualified real estate experts familiar with the district, securing the estimate of each as to the reasonable development period for each zone, and striking an average representing their combined judgment. The third item was formerly handled in a similar manner, but an official re-appraisal of all property in the county by a force of competent appraisers has made this unnecessary.

#### COMPUTATION OF ASSESSMENTS

The detailed procedure in distributing the district assessment for a trunk sewer on these principles is as follows:

1.—*Present and Future Excess Cost.*—Estimate the total present and future excess cost of all trunk and branch sewers of the system above the part of such cost which will be assessed on abutting property for local service.

2.—*Sub-Districts.*—Divide the district into sub-districts (for purposes of assessment only), each of which includes the whole area served by an extension or branch larger than 8 in., or which contributes either directly or by 8-in. laterals to the main trunk.

3.—*Time Zones.*—Divide these sub-districts into the several time zones representing the period when service is expected to be provided, such as "immediate", "2 years", "5 years", etc.

4.—*Accessibility*.—Apportion the total present and future excess cost to the several sub-districts in proportion to area, and deduct from the amount charged to each sub-district its own estimated excess future extension or branch main cost.

5.—*Time*.—Divide the amount thus apportioned to each sub-district among the several time zones therein and multiply the share of each zone by the present worth of one dollar for the period assumed for that zone. Add the results and determine the percentage relation of each to their sum. Apportion the total present district assessment over the zones in the ratio thus established.

6.—*Valuation*.—It is not practicable to correct each individual property for valuation. Areas of approximately equal unit value are laid out and a fair average is used for each. The apportionment for each area is then computed from the accessibility and time results and multiplied by a factor equal to the square root of the quotient of the valuation per acre of that area divided by the lowest valuation per acre of any area in the district, or,

$$F = \sqrt{\frac{V}{V_{\min}}} \dots \dots \dots (1)$$

in which,  $F$  is the factor applied to any area,  $A$ ;  $V$  is the valuation per acre in  $A$ ; and  $V_{\min}$  is the lowest valuation per acre of any area within the district. The percentage relation of each result to their sum is determined, and this percentage, applied to the total amount of the present district assessment, gives the amount to be levied on each valuation area. From this, the rate per acre is readily determined and the apportionment for each property is a simple matter.

In most districts there are both platted and unplatted areas. In order to avoid discrimination against the latter, a reduction of 15 to 20% is made in all unplatted areas to allow for future streets. In platted territory, after fixing the total amount to be collected from each valuation area, this amount is distributed, using frontage, or more correctly, average lot width, as a general guide, this usually appearing to represent an equitable division. In some unusual cases, a combination of frontage and area has been used, but, with ordinary regular platting, this is unnecessary. Occasionally, some local condition requires special consideration; but, in general, assessments can be computed by the method described with satisfactory results.

These computations are not as difficult or complex as they seem. In the case of large districts they require a considerable amount of time and effort, but if they result in a fair and equitable solution of the problem, it is worth while. It may be mentioned that in the practical application of this method, it has been found that the assessments levied against outlying property not now given actual service, approximate reasonably the cost of the additional capacity provided to meet their future needs.

#### TYPICAL COMPUTATIONS

The process may be made more clear by the following example of an actual assessment in Franklin County, Ohio, covering one of the smaller projects. It will be seen that it results in placing the weight of the assessment on the

valuable and immediate property and reducing the burden on the cheap and distant land to a small figure.

EXPLANATION OF TABLES

Table 1 contains the computations to determine the preliminary apportionment of costs on the basis of accessibility. The average rate per acre

(present and future), is found to be  $\frac{14\,338.26}{622.85} = 23.02$ . The values in Column (4) are the products of Columns (2) and (3), and show the amount which would have been chargeable to each sub-district (subject to correction for valuation) if the complete system had been constructed at this time. Column (5) shows the estimated excess cost of the future mains in each sub-district. Sub-District F is the area of present service. Column (6) is compiled by subtracting Column (5) from Column (4) for each sub-district, crediting each sub-district with its future expense.

The effect of time in the adjustment of excess costs is computed as shown in Table 2. Column (1) designates the division of Sub-Districts A, B, C, etc., into zones that will feel the benefits of the improvement in various estimated periods of time. The corresponding time intervals are listed in Column (2). Column (3) lists the area of each zone. Columns (4) and (5) correspond to Columns (2) and (6) in Table 1. Column (6) gives the present worth of \$1.00 at the end of the time interval indicated. Column (3) divided by Column (4) and the result multiplied by Column (5) gives the adjusted preliminary apportionment for each zone, and this multiplied by Column (6) gives the results shown in Column (7), or,

$$\text{Column (7)} = \frac{\text{Column (3)}}{\text{Column (4)}} \times \text{Column (5)} \times \text{Column (6)}$$

The total of Column (7) is, of course, less than the amount to be assessed and it is, therefore, proportionally expanded to the correct amount as indicated in Columns (8) and (9).

TABLE 3.—VALUATION.

Totals.	.....	622.85	.....	.....	.....	\$23 067.30	100.00	\$11 607.63

Finally, the computations for the determination of the valuation correction are given in Table 3. It will be noted that some of the zones in Column (1) have been further subdivided in order to allow for a difference in valuation. In Column (2) are listed the values of the various areas per acre. The acreage of each valuation area is given in Column (3) and, for convenience in computation, Column (3), Table 2, is repeated as Column (4). Column (5) is a duplication of Column (9), Table 2. In Column (6) are listed the values of the factor,  $F$ , which equals  $\sqrt{\frac{\text{Column (2)}}{200}}$ . Column (3) divided by Column (4) and the result multiplied by Column (5) gives the time assessment for each valuation area and this multiplied by Column (6) makes a preliminary correction for value, shown in Column (7), or,

$$\text{Column (7)} = \frac{\text{Column (3)}}{\text{Column (4)}} \times \text{Column (5)} \times \text{Column (6)}$$

The total of Column (7) being greater than the amount to be collected, the items are reduced proportionally as indicated in Columns (8) and (9). Column (9) of Table 3 gives the amounts to be assessed in each area, and all that remains is to distribute them over the individual properties within the areas, the rate per acre being fixed by dividing each amount by the number of acres in its particular area, or,

$$\text{Rate per acre} = \frac{\text{Column (9)}}{\text{Column (3)}}$$

#### STORM SEWER ASSESSMENTS

In the case of storm sewers special consideration must be given to land relieved of overflow conditions or otherwise benefited to a greater degree than other property, but if this feature is taken care of in a manner similar to local service cost as described in the detailed procedure previously outlined, the same methods can be thereafter used.

#### ASSESSMENTS FOR WATER MAINS

Water mains present a different problem in one regard, that is, that the boundaries of the district to be served are not fixed as in the case of a sewer. It has been found that the only practicable and satisfactory method is to lay out a definite area on both sides of each main, covering a reasonable zone of influence with reference to other present or future mains, and ignore the inevitable circulation and overlapping of service through the several feeders, assuming the benefit of each to extend to a line between such feeders at a distance fairly representing the proportionate capacity. This being determined, the regular method may be used.

#### CONCLUSION

The system described has been in use for several years. In general, it has seemed to meet with public approval, and no difficulty has been found in explaining it in simple language to the average property owner. Many expressions of approval of the principles involved have been received from such owners as well as from attorneys and engineers. It is presented for consideration and discussion as an attempt to solve, as far as may be, a problem which has apparently heretofore received less attention than its importance merits.

## DISCUSSION

O. BONNEY,\* ASSOC. M. AM. SOC. C. E.—In connection with this paper it might be of interest if some of the points mentioned were discussed briefly from the standpoint of a representative of a municipality, of approximately 300 000 population, engaged in furnishing sewerage and water service to several such county sewer districts.

Recent estimates by the U. S. Census Bureau credit Columbus, Ohio, with a population of 291 000 as of July 1, 1927, the area of the city being approximately 32.5 sq. miles. The trend of development in and around the city is principally north, northwest, and east, which makes it necessary for sewage from practically all the Franklin County Sewer Districts to be transported and disposed of by the sewers and sewage disposal works of Columbus. Plans by the City, for intercepting sewers, relief sewers, and sewage treatment, contemplate provision of capacity for sewage from about 59 sq. miles outside the present city, a large part of this area being in established county sewer districts. To date, about 78 miles of sewers have been constructed under the jurisdiction of the County Sanitary Engineer, of which, about 51 miles are tributary to the sewerage system of the City of Columbus.

The City charges the population, residing in county sewer districts and in suburban villages adjacent thereto, tributary to its sewerage system, an amount which is arrived at in accordance with the following rate schedule: \$4.00 per year for single houses; \$3.50 per year for each side of a double house; \$3.00 per year for each apartment of an apartment house; and \$1.00 per employee per year in the case of stores or factories, the number of employees being based on the average number employed during a six months' period.

There are now (1927) approximately 10 000 persons in county sewer districts and in suburban villages tributary to the sewerage system of the city, who are paying annual charges to the City in accordance with these rates.

The rates now in use were established several years ago and were based on approximate estimates, and some officials have raised the question as to whether or not they do represent an adequate return to the city as measured by the money invested and the service rendered. The City is now making a comprehensive study of the situation with a view toward the establishment of a rate for transportation, pumping, and treating sewage from county sewer districts and suburban villages, which at once will be fair and equitable to all parties concerned and which will be based on the cost of construction, operation, and maintenance. This problem is being approached in accordance with established valuation and rate-making principles.

Close co-operation is maintained between the County and the City with respect to basic design assumptions, boundaries of districts, etc., and while the rates of sewage flow, ground-water infiltration, etc., provided for are not identically the same, results—which to all intents and purposes are in close agreement—are reached. In the matter of the allowance for ground-water infiltration there is considerable difference between the rates used by the

\* Sewerage Relief Engr., City of Columbus, Columbus, Ohio.

County and the City. Mr. Bradbury has stated that he provides capacity for 3 000 gal. per acre per day, while 750 gal. per acre per day—equivalent to about 25 000 or 30 000 gal. per mile of sewer per day—is provided for by the City.

There is perhaps some question as to the allowance of 3 000 gal. per acre per day. This is a higher figure than is commonly used, but conditions in some districts contiguous to the city may justify it. For some time there has been a doubt in the speaker's mind as to the sufficiency of the City's allowance. In one or two instances there have been indications that ground-water leakage exceeded 750 gal. per acre per day. In some districts in the city served by separate sanitary sewers and storm drains, considerable overloading of the sanitary sewers takes place during wet weather. To a certain extent ground-water infiltration no doubt accounts for some of the overloading, but roof water connections and the entrance of surface water make it practically impossible even to estimate approximately the quantity. Efforts are being made by the City to disconnect the roof water and surface water connections, and once this is accomplished infiltration measurements can be made. On about 15 miles of sanitary sewers now (1927) under construction in the city every precaution is being taken to reduce ground-water infiltration. A type of pre-cast asphalt gasket is being used in the joints, 3-ft. lengths of pipe are being installed, and special attention is being paid to manhole construction. When this work is completed and before house connections have been made to it, it is planned to attempt to measure the leakage during a wet season.

In regard to the assessment of cost in proportion to benefits, Mr. Bradbury has presented what might appear to be a complex method of measuring the benefits derived by the installation of sewers and has shown it to be very simple in operation. It seems fitting and proper that the element of value before and after the sewer has been installed should be considered, and his method of handling this factor would seem to be just and equitable to all. It has not been the City's custom to adjust assessments on the basis of valuation. Ordinarily, 98% of the cost of sanitary sewers is assessed against the property benefited—2% being borne by the city at large. The 98% is usually distributed over the district in proportion to frontage benefits. In the case of storm drains the practice on the part of the City has been somewhat varied. In some cases the property benefited has been assessed the entire cost minus 2% plus the cost of drains in street and alley intersections and, in some instances, the entire cost has been carried by the city at large.

It is contended by some that the installation of sewers and water mains in county sewer districts contiguous to a municipal corporation operates to the disadvantage of the municipality in that a district once provided with sewer and water facilities and other utilities is not particularly desirous of being annexed to the municipality. This may be true to some extent but usually the advantages to a community to be derived by annexation overbalance any possible disadvantages; hence, when the district does come into the city it represents an asset to it in the way of complete and well-designed and constructed water and sewerage systems. Certainly a municipality is fortunate in having the extensions of its sewerage and water systems into

county territory made under capable engineering supervision. Annexations to the City of Columbus since 1920 total approximately 11 sq. miles, which would indicate to some extent at least that the city is continuing its former steady growth in area and that the construction of sewers and water mains under the County Sewer District Law has not been disadvantageous to the city.

R. F. MACDOWELL,\* M. A. M. Soc. C. E.—The Sewer District Law, as originally adopted by the Ohio Legislature in 1911, was a rather crude and unworkable tool; but it contained the basic elements of a most needed and useful instrument. There was required only the refining effects of protests, Court actions, the experiences of use, and several legislative amendments over a period of seventeen years, to make it what is now felt to be a practically impregnable act. It meets a real public need in connection with the development of property for residential purposes in the suburban areas surrounding the larger centers of population. Other States would do well to profit from Ohio's experience in the creation and operation of its Sewer District Law.

To show the extent to which the law is being utilized in Ohio, it was estimated, that when the law was in jeopardy for several months preceding the 1926-27 session of the Ohio Legislature, water and sewer improvements costing approximately \$50 000 000 were under way or contemplated under the law in the twenty or more counties of the State which had established sewer districts. The development of the law and the use being made of it, are but a natural outcome of the tendency of urban residents to get out into the open spaces surrounding the cities proper when building their homes. Not only are the unincorporated areas surrounding the larger cities of Ohio taking advantage of the law, but many of the suburban villages are utilizing it to finance water and sewer improvements which their taxing limitations would otherwise prevent. The law has also been of especial service to summer resort communities, from which much typhoid previously emanated due to bad sanitary conditions. These resorts are being rapidly cleaned up and given modern conveniences by the help of the law.

The determination of the proper boundaries of a sewer district (or the area to be assessed for any improvement) is, as Mr. Bradbury states, a difficult one because it depends on judgment as to the probable development of the territory in the future. It would obviously be unjust to assess for a trunk sewer the area of an entire township (if such area happened to be on the water-shed of such trunk) when only a small part of the area is immediately benefited. On the other hand, the engineer must be firm in including, within an assessment district, farm land which is immediately adjacent to and in the line of subdivision development, and is, therefore, quite obviously benefited by the improvement in spite of most vociferous protests to the contrary by the present property owners who are thinking of benefits solely in terms of added income from the sale of crops. Under the Ohio Sewer District Law, the Courts will undoubtedly uphold any assessment if the engineer has been reasonable.

---

\* Civ. and San. Engr., Cleveland, Ohio.

As regards the basis of design for sewers, especially that of per capita flow, the speaker believes with Mr. Bradbury that it is necessary to be quite generous in making allowance for concentration of development and also for ground-water infiltration. The speaker finds the curves of maximum, as compared with average, flows in sewers—as prepared by Robert B. Morse, M. Am. Soc. C. E.—to be quite useful and safe for small sewers. The matter of ground-water infiltration is a serious one, and should always be given careful consideration, depending on the character of the soil and the normal ground-water level. Although bituminous materials have been used for sewer joints for many years, their general use has developed only recently. This has resulted in a flooding of the market with many bituminous compounds, some of which are almost worthless, and the engineer must be prepared to approve only those which will be effective. A reputable testing laboratory at Cleveland, in co-operation with the speaker, has prepared the following specifications for bituminous compounds and the speaker requires that any such compound proposed for use in sewers must meet these specifications:

"The compound shall consist of bituminous material mixed with mineral matter. It shall melt and flow freely at 250° Fahr., and shall show no loss in weight when brought to a temperature of 400° Fahr. It shall adhere firmly to glazed surfaces of pipes, sufficiently to withstand 10 lb. internal pressure under conditions obtaining in practice. When set it shall have sufficient elasticity to permit of slight lateral flexure without injury to the joints or breaking the adhesion to the pipes.

"The amount of bituminous material extracted by carbon bisulfide shall not be less than 40% and the weight of mineral matter determined as ash shall not exceed 50 per cent.

"It shall show no deterioration of any kind when immersed for a period of 5 days in a 1% solution of hydrochloric acid or in a 5% solution of caustic potash."

A pre-cast bituminous joint has been developed recently which the speaker believes to be a progressive step, although its efficiency depends to quite an extent on the skill and care with which it is pressed "home" to fill the joint. Until a sewer pipe joint has been developed which is "fool-proof" and certain to make a tight joint, under ordinary conditions of placing, ground-water infiltration will continue, and, in designing sewers, the engineer should make a generous allowance for this factor.

The major part of Mr. Bradbury's paper covers the subject of special assessments, and rightfully so, as Mr. Bradbury has spent a great deal of time and has developed much original thought on the subject. In reading much of the available literature on the subject, the speaker has been impressed with the fact, that, as Mr. Bradbury states, the problems involved in special assessments have never been thoroughly analyzed. At least, no hard-and-fast rules, and but few basic principles, seem to be generally accepted. There is a wide divergence of opinion as to what elements make up special benefits and various methods are, therefore, in force in different parts of the United States. This is probably due, in part, to the fact that variation is necessary in order to conform to local conditions as well as to type of improvement.

Quoting a well-expressed definition of special assessments, they are "compulsory contributions paid once and for all to defray the cost of a specific

improvement to property, undertaken in the public interest, and levied by the Government in proportion to the special benefits accruing to the property owners". Another defines them as "general proportional contributions of wealth levied against land and collected from its owners and occupants to defray the costs of specified public improvements made, or of specified public service undertaken, in the interest of the general public."

Special assessments differ from general taxes in that the latter are levied to provide for all general public needs, whereas the former are levied to meet some special need of property situated in an area created for the express purpose of such levy and possessing no other purpose. Furthermore, taxes are levied continuously, while special assessments are exceptional, as to time as well as locality, and should be made only where the property assessed is actually increased in value to an extent at least equal to the amount of the assessment.

In one sense, almost all public improvements especially benefit some individual or a part of the people of any community. It thus becomes a matter of judgment how far to go in making special assessments. For example, the creation and maintenance of parks are financed in the City of St. Louis, Mo., by special assessment within definite park districts. Likewise, the City of Cleveland is now installing "white way" lighting systems, the cost of which is assessed on the property benefited thereby. Special assessments are also being used over the United States for financing irrigation, drainage, excess condemnation, re-paving, and rapid transit as well as water, sewers, sidewalks, paving, and grading improvements. Thus, it may be stated that the special assessment method of financing public improvements is gaining in favor. This is probably due to general tax limitations, and also to the fact that it is being more and more recognized that special assessments place the burden directly on the property benefited. The problem is in determining what property is benefited, and to what extent.

The relative amount of the assessment in each case rests with the engineer, or with a group of special appraisers, and although it is practically impossible for them to secure ideal justice for every one affected, results may be obtained by careful thought and intention to a few basic principles, which cannot be criticized and, therefore, will not be invalidated by the Courts.

Although it is fundamental that any property which is not especially benefited by an improvement should not be especially assessed, it is equally true that all property which receives some benefit should receive some part of the assessment. All public, quasi-public, or private property seems to be assessable when benefited, such as schools, cemeteries, churches, parks, and railroad rights of way. It seems to be recognized that any exemption of benefited property from assessment is unsound, and the assessment should be spread where the benefit rests, whether such benefit be to the general public or to a private individual, and any exemption from assessment places an added burden on the remainder of the property to be assessed.

Although the topographic and other natural features of the property are quite often made the cause of reductions of the special assessments, some Courts seem to hold that no variation in the unit assessment need be made

on this account. One Court has decided, for example, that a lot which lies below the level of the street to be improved, does not benefit less than the adjoining lot at the street level, as the improvement is there, to be taken advantage of by filling the property, and the assessment for such lot, therefore, was upheld. Some authorities and also some Courts, however, disagree with this reasoning, stating that the assessment for such lot should be reduced to some extent.

There are also other reductions which should be made. For example, where allotted and unallotted lands are being assessed for the same improvement, a part of the latter should be exempted, equivalent to the average area which is in streets in the allotted section, and is thus free from assessment.

The power to levy special assessments is generally held by the Courts to be a continuous one; that is, as many assessments may be made on any parcel of land, for benefits derived from various extensions to any improvement, as may be necessary, so long as special benefits can be shown from each assessment. This principle may be taken advantage of, for example, in a progressive program of sewer construction extending over a term of years, to complete a sewer system with a single main outlet. The outlying territory to be ultimately drained by the main trunk sewer may be assessed for its reasonable proportion of the cost of each part of the outlet, interceptor, trunk, or lateral sewer until the local service pipe is provided. Such assessments, however, should always be made so that the entire area drained by the system will be assessed an approximately equal amount, as of the date when the local service is obtained.

Although there are many factors involved in the determination of proportional benefits, as shown by Mr. Bradbury, the speaker wishes particularly to mention the use of valuation. The author has developed a method for the use of valuation of land as a factor in determining the proper apportionment of assessments, which is quite unique and deserves recognition. There is no doubt in the speaker's opinion that valuation, if properly applied, leads in the direction of ideal justice in the computing of assessments. There are, however, many difficulties as well as objections to its use, which, for purposes of discussion, the speaker wishes to emphasize.

When valuation is used, the assessment is distributed in proportion to the assessed valuation of the land at the time the improvement is made, or some proportion of such valuation. Quoting from the *National Municipal Review* of February, 1922:

"It favors cheap land at the expense of dear land and fails to recognize that the present value of land is due to conditions existing before the improvement is contemplated or completed and that these conditions may be completely altered by the improvement."

And, it may be added, by other conditions arising after the assessment is made. In other words, the valuation method, although in some cases particularly adaptable to the securing of equitable assessments in proportion to benefits, is unstable when compared with the area and the foot frontage, as these do not change from time to time, as does the valuation of property. Special assessments should always be levied so as to produce equal and uniform justice

throughout the life of the improvement. It is for this reason that no consideration should be given to built-up as compared to vacant land, as the benefit is the same in each case.

The use of valuation may result in unjust assessment as the valuation of property may change rapidly, due to private improvements, whereas the benefit from the public improvements is nearly the same for improved as for unimproved property; also, valuations are often unreal and unjust and decidedly not up to date, if taken from the tax duplicate, or merely the present judgment of one or more men, in case real estate experts are called in to pass on the matter.

The author's line of reasoning as regards the use of valuation is quite logical but the speaker believes that valuation cannot be used with surety that justice is being served. The determination of relative valuations is arbitrary and assessments made with valuation as a factor will be likewise arbitrary. High-class property should not necessarily be assessed more than low class, merely because it is more valuable, because often the so-called low-class property is made high class merely by the addition of water and sewer improvements. It is agreed that the use made of land is not a measure of benefit, but surely it affects its value. Therefore, does it not follow that value in itself is not a measure of benefit? On the other hand, there is no doubt that enhancement of value by reason of improvements is a true measure of the special benefit to property, or that failure to use land should not relieve the owner from assessment. However, property enhances in value from improvements in proportion to its accessibility and the time in the future when use will be made of the improvement. If these factors, as well as the topography or usable area of the property, are properly taken into consideration, there is doubt as to whether the valuation factor as proposed by the author does not carry the decimal point too far, as it were; especially is this true when the relative valuation of the various parcels must be first assumed and then an arbitrary assumption made that the values vary in proportion to the square root.

F. D. STEWART,\* ASSOC. M. AM. SOC. C. E.—The Ohio Statutes require the approval—by the State Department of Health—of all plans of public water supply and sewerage improvements within the State and, consequently, the Department is brought into close contact with the work of the various counties in installing these improvements. The speaker has been associated with that Department since about 1920 and has been in a position to see the operation of the County Sewer District Law expand from its original small proportions to its present status.

It has been noted by Mr. Bradbury that the bulk of the work being done by counties is in territory contiguous to the larger cities. The value of having sewerage and water improvements designed and installed in a logical and comprehensive manner and in conformity with the same utilities of the adjacent city cannot be over-estimated. To any one familiar with the difficulty of securing proper sanitation in suburban areas the advantages of such a central

\* Asst. Engr., State Dept. of Health, Columbus, Ohio.

working authority, as this law provides, is apparent. Without proper sewerage and water supply the areas will abound with unsafe wells (either contaminated or subject to contamination), cesspools, septic tanks, and misused storm drains, with resultant nuisances. In counties well organized for this work, sanitary improvements now precede to a greater or less extent the actual occupation of the outlying areas of cities. It is true that the county officials, in establishing the boundaries of sewer districts and designing the improvements, must guard against being unduly influenced by the optimism of realtors, but if good sound judgment is exercised no real injustice in the way of assessments will occur. Furthermore, the law as it stands to-day provides ample recourse to any property owner who does not consider the action of the county right or just, either in the inclusion of his property in the district or in the tentative assessment.

The law which provides for the inclusion of parts of municipalities in county sewer districts has been found to be of great advantage. This permits the solution of sewerage problems in accordance with topography without limitations of corporate boundaries. In most instances this has been of greatest value to the cities in providing sewer outlets for territory within the city boundaries inaccessible to existing sewerage improvements.

There are in Ohio a number of summer resorts located along the shore of Lake Erie and around small inland bodies of water to which there is a large influx of people during the summer season. These resorts are generally remote from the centers of population and their sanitation as it relates to water supply and sewerage presents a most perplexing problem. The outdoor privy vault, formerly associated with summer vacationing, is now barely tolerated, and the demand for modern conveniences is insistent. It is here that the County Sewer District Law can function to a distinct advantage as the areas are usually unincorporated. In fact, it has been found in Ohio that in no other way can proper sewerage and water supply improvements be installed. The real obstacle in securing installation of improvements is the item of cost. The property is usually of lower value than city property. Also, the use of the adjacent bodies of water for bathing may render the disposal of sewage difficult and costly. The problem, therefore, calls for the exercise of the best engineering skill and economy of design and construction.

The existence of the County Sewer District Law often provides a means of securing sewerage and sewage disposal for small municipalities which are hampered by statutory debt and tax limitations. The municipal authorities may petition the county commissioners to include the municipality as a whole or part of a county sewer district, and thereupon the county may install the improvements and assess the cost directly on the benefited property.

The law vests with the county commissioners the authority to initiate work under the County Sewer District Law. Nevertheless, it has become a custom in the State to require a petition from a percentage, and usually in the case of local improvements, a majority, of property owners to be benefited by immediate installations. Occasionally, a board of county commissioners will refuse to act in this regard for areas obviously in need of improvements, even on receiving petitions from a large percentage of property owners. Relief

from such a situation is afforded by the Ohio General Code. This provides that whenever formal complaint by constituted authorities is made with reference to unsanitary conditions in any area outside of corporate municipalities, the State Director of Health shall investigate the complaint in order to substantiate the claim. If conditions are found as alleged, the State Department of Health may order the establishment of a county sewer district by the county commissioners—to include the area concerning which complaint has been made—and the installation of sewerage therein.

The law further provides that on failure to comply with such an order of the State Department of Health, the Act may be enforced by a writ of mandamus issued by any Court authorized to issue such writs. Similar action may be taken with respect to water supply improvements in accordance with Sections 6602-28 to 6602-30, inclusive. The law provides further for appeal from such an order, either to referee engineers to determine the necessity of the order or to the State Supreme Court by petition in error.

W. M. OLSON,\* Assoc. M. Am. Soc. C. E. (by letter).—The author makes clear the admirable procedure in Ohio, by which suburban or rural property is assessed for water or sewer mains. Such procedure is impossible in Illinois. Existing laws enable incorporated cities, towns, and villages to construct water and sewer mains and to assess the cost on property benefited. Sanitary districts to provide for sewage disposal through a common outlet may be organized to include incorporated municipalities and unincorporated areas within three miles of included corporations, but no provision is made for the construction, by public means, of water mains or sewer laterals in any unincorporated territory.

The construction of sewers by private capital is possible, but rarely ever practiced because of the difficulty of getting a reasonably large proportion of individual property owners to agree to share the cost. In some cases, real estate operators developing a new area construct some sort of sewer system. Water pipe is sometimes laid by private capital, either by real estate operators, who may construct reasonably adequate systems offering some measure of fire protection; or by "water associations" which lay small pipe to provide domestic water service only to areas adjacent to a public water system.

Unfortunately, the State Department of Public Health is not authorized to exercise adequate supervision over the construction of sewers and water mains. Most municipalities co-operate voluntarily with the Department of Public Health. Experience has demonstrated, however, that private agencies cannot be relied upon to co-operate, and this makes the private construction of sewer and water utilities especially undesirable. To make matters worse, there is no provision for regulations covering zoning, housing, and building construction in unincorporated territory.

As a result of these laws, or this lack of laws, the following conditions may obtain in unincorporated territory: (1) Unscrupulous real estate men and "home builders" may learn that they are free to do practically as they please, and may proceed to do so with a vengeance; (2) entire areas may be

\* Res. Engr., Pearse, Greeley & Hansen, Chicago, Ill.

built up solidly without sanitary sewerage or proper water supply; and (3) an area may be included in, and taxed by, a sanitary district but may not receive any direct benefit.

This is just what has happened in many places in Cook County. In 1921, Acacia Park, which was covered largely by truck gardens, was annexed to the Sanitary District of Chicago. About five years later, an ill-advised attempt to incorporate as a tiny village (120 acres) failed. In the absence of proper regulation, it has been a builders' paradise. Houses have sprung up as if by magic. On November 8, 1928, a count of houses within a most densely built-up 80 acres, revealed 370 buildings. Of these, 11 were used for commercial purposes (7 one-story frame, 1 two-story frame, and 3 one-story brick), and 359 were residences (130 one-story frame, 72 one and one-half-story frame, 5 two-story frame, 112 one-story brick, and 40 one and one-half-story brick). Most of the houses are set close together on 30-ft. lots in groups separated by series of vacant lots. There are many good-looking small houses interspersed by a few architectural atrocities. The intensity of use of this area may be indicated by noting that there are 4.6 houses per acre. Zoning ordinances of eight of the better-class suburbs in the county (according to the Chicago Regional Planning Association), specify a maximum population density of 6 families per acre. A house on every lot in Acacia Park will approximate 8 families per acre.

Natural drainage, which is none too good, has been supplemented by farm tile, laid before subdivision, and by makeshift street drains laid since. Existing facilities are entirely inadequate to remove storm run-off promptly. There is a safe domestic water supply distributed privately from the Chicago System, but no fire protection is provided. The fire hazard is enormous.

Practically all the houses have modern plumbing, discharging, supposedly, to individual septic tanks, which, in turn, are connected to the drainage system. Many of the so-called septic tanks are no larger than ordinary kitchen catch-basins, and some houses undoubtedly discharge raw sewage into the road drains.

Extensive building construction has occurred in spite of the fact that reputable banks refuse to loan money for the construction of residences on lots not served by a proper sanitary sewer system, and by a public water supply affording adequate fire protection. Small local banks closely affiliated with building organizations financed the work. The sale of houses was accelerated by the true statement that "You will have no city taxes to pay".

In the spring of 1928, an adjacent area similar to Acacia Park was annexed to the City of Chicago. The Chicago Board of Local Improvements is already making preliminary studies of proposed sewerage and has found that a long and expensive outfall sewer will be required. Acacia Park is particularly unfortunate in not having been included in this annexation, since a comprehensive sewer plan for the entire built-up area probably could have been devised to use a single outlet. As it is, the City of Chicago can make no provision for Acacia Park in its proposed plan, since the law does not permit such construction.

As the result of the lack of sewerage, the usual unpleasant and unhealthful conditions are present. The relatively few basements are flooded after every rain of any consequence. Some enterprising owners have installed electric pumps to discharge the "water" into the alley. In wet weather, heavy trucks break through unpaved roads and crush the shallow drainage lines. Sewage effluent rises to the surface and ponds on adjacent low-lying land. If the breakage of a drainage line causes private septic tanks to overflow, interested persons may repair the break. If not, a complaint may be made to the health officer. Untrapped storm-water inlets emit the odors of decomposing wastes lodged in tile lines laid to no particular grade or alignment and without manholes for cleaning. Even in cool weather, sewage odors may be observed at various places in the community. In hot weather, nuisances abound, and frequent complaints are made to the health officer. In the absence of a sewer system, there is but little for him to do. He cannot indict the whole community. The relative absence of typhoid fever may be explained only by the safe water and milk supplies and by a large measure of good fortune.

With the growth of Acacia Park, conditions will become worse. Private septic tanks, usually installed with the supposition that no cleaning will be necessary, will have to be cleaned to relieve clogging. Nuisances now grievous will become unbearable, and annexation to the city must follow. At that time, the waste of money on temporary sewage disposal will be made clear and will stand out as a convincing indictment of the financial policy which permitted the expenditure of large sums on extensive building operations previous to the construction of necessary sanitary utilities.

The foregoing is intended to show that, in the Chicago Region, the problem of providing necessary sanitary facilities for closely built-up unincorporated areas is acute, and as yet unsolved. New enabling legislation is needed. Procedure similar to that in Ohio should be authorized, or existing sanitary districts should be empowered to construct lateral sewers where necessary and to assess the cost against property benefited. Legislation prohibiting the sale of lots for residence purposes until water and sewer mains have been installed according to plans approved by the Department of Public Health might be justified by modern conditions, but would probably be considered an unwarranted invasion of the rights of private property.

FRANK C. TOLLES,\* M. Am. Soc. C. E. (by letter).—This paper is devoted, first, to an outline of the provisions of the statutes which enable sanitary improvements in suburban Ohio; and, second, to a description of a procedure of assessment. The Enabling Act mentioned by the author is purely local, but in so far as it may be used as a guide for others, it is proper to comment on certain phases of it.

The failure of the 1913 statutes to include provisions for detailed and specific advice to property owners of the terms and of the costs of the undertaking, led to objection on constitutional grounds and resulted in later amendment. The law now requires as a precedent to critical legislation, that there shall be prepared detailed plans, estimates of cost, and tentative assessments.

\* Civ. Engr. with George B. Gascoigne, Cleveland, Ohio.

Individual notice of these is given to each property owner whose address is known. In a project of wide scope this procedure is burdensome. However, and despite the burden of the preparatory work, improvements have been carried on under the Revised Act, although possibly with stricter regard for proved needs. Irrespective of its legal aspect, the statute requirement affords sound protection to the property owner, and it has served to restrict the more speculative developments which, for a time, threatened to bring Ohio sanitary districts into disrepute. From the administrative side, it would be desirable if the preparatory engineering could be lessened. Particularly is this the case in the smaller counties which do not maintain sanitary engineering departments, and in which interest in suburban development is sporadic.

It is noteworthy that the provision of the law for assessing interest charges instead of making these a levy against income, serves to lessen operation costs, and thus favors the direct consumer or user. This feature is helpful in establishing the district as a going concern.

There is still in the law a provision for paying to the county commissioners who authorize the improvement, certain fees which are proportioned on the improvement cost. These fees are small (one-third to one-tenth of 1%, with a fixed maximum), but it would be better if the payments were not so intimately related to the size of the project.

To Mr. Bradbury's statement of the extent of improvements which have been installed under the Ohio law, should be added the fact that, in one or two counties, the auditors' records carry some rather long lists of delinquents in the payments of assessments under the District Act. This fact may reflect a temporary condition in a local real estate market, or it may indicate a too rapid and unwise extension of improvements. This comment is not directed to Franklin County, in which Mr. Bradbury is County Sanitary Engineer.

*The Method of Assessing.*—The major consideration in the paper concerns a method of apportioning construction costs. Although developed to fit particular statutes and precedents, the method is mathematically, and probably legally, applicable in the general case of spreading costs over a district. To those who have studied this subject, Mr. Bradbury's contribution is welcome as helping to clarify a very "muddled" and unsatisfactory situation. It is, however, open to certain criticisms of practice.

Assessments which proceed from the powers of the Government must be levied in the manner prescribed by enabling laws. The statutes which cover the County Sewer Districts of Ohio recite that, in the case of main works, property which abuts the improvement may be assessed for local service, and that the remaining cost, less any county share, shall be spread as a district assessment on all property in the district and in accordance with special benefits. Other Ohio statutes which relate to municipal improvements provide that special assessments be levied (1) by percentage of tax value; (2) in proportion to benefits; or (3) by the foot front. There is a further provision in the Municipal Code that the sum total of special assessments within a 5-year period shall not exceed one-third the value of the property after the improvements are made. Assessments for other purposes or by other Governmental

units are generally by benefits. The mass of legal decisions is found in municipal operations.

In Ohio, the tendency has generally been to apportion assessed costs in proportion to some readily established physical characteristic, including area, frontage, distance from the improvement, or a combination of these. In cases where levies have been made on the basis of benefits, the computation has sometimes been roughly estimated in terms of area or other characteristic and then modified to meet the judgment of the assessor. In other cases, the so-called "point system" has been used to yield a proportionate and relative estimate of benefits. For small improvements on which the assessors are well acquainted with the individual properties this latter method affords reasonably good results.

*The Bradbury Formula.*—Whereas assessments spread to physical characteristics are readily determinable and comparatively simple of application, those based on benefit must be distributed by exercise of judgment and to meet several factors, which in the aggregate, at least, are rather intangible. Mr. Bradbury's method does not eliminate judgment, but through itemization of elements, focuses judgment on a particular point. In essence, the plan is to make the assessment proportionate to the product of: (1) Ultimate cost less future expenditure; (2) a factor of deferred use; and (3) the square root of a value ratio.

As an expression of individual opinion there is no reason why this method should not be as good as any other reasonable rule. When it is coupled with assessment for local service on a frontage or area basis, the method admits influence by different variables. It, therefore, minimizes the inequities that result from distributing the assessed cost according to any single characteristic. However, any conclusion that assessments computed by Mr. Bradbury's method are more equitable than those determined by physical characteristics alone, is predicated on the assumption that the fundamental data are reasonably accurate. In spreading assessments as described by the author, it is necessary to evaluate certain factors, thus:

- (a) The total ultimate cost of the improvement when—at some future and unknown date—it is completed.
- (b) The time sequence—perhaps by 3 or 5-year increments—when different parts of the improvement will be required, and this for a total future period of, say, 20 years.
- (c) The present value of the land which is to be assessed.

The first of these factors—the eventual cost—is within the range of reasonable estimation, although there should be taken into account the occasional practice, in rural development, of preceding sanitary improvements with pavements. It is conceivable, however, that such estimates would average within an error of 15 per cent.

The time element is rather more difficult to fix; that is to say, for example, that a given sub-district will require trunk outlets or plant facilities in 1945. An error in assigning a sub-area to a 10-year time zone instead of to a 15-year zone might lead to a unit assessment which departs by about 20% from that which might prove more equitable. A rough visualization of this is afforded

by comparing the partial assessments in Column (9) of Table 2, for the approximately similar zones E 1, E 2, and E 3, which represent 2-year time differentials.

Assessments are admittedly based on judgment, and it is perhaps not fair to subject the expression of such judgment to more or less mathematical scrutiny, for Mr. Bradbury has undertaken not to point off the decimal, but rather to make determinations rational and comparable. However, the writer has recently made some assessment studies in which the estimate of the time factor was attempted, and he was struck with the discordances of opinion among those whose judgment was pertinent. Faced with the question, "When will this particular area need sewerage", well-informed officials, engineers, and conservative realtors gave answers that differed by ten years, and that further yielded no very clear indication of a preponderance of opinion. In small areas, and with a well marked trend of development, better accord would be expected.

In the matter of setting a value (Mr. Bradbury's third factor), there exists considerable opportunity for variation. Since valuation is itself an expression of judgment, rather than an agreed or barter price, it is subject to all the influences of personal error whether it be from tax duplicate or the result of special appraisal. Also, is the fact that county sewer district improvements are sought by areas which are in process of change from quasi-farm land to sections of suburban development. This betokens a state of flux with a corresponding effect on values, and the resulting difficulties in valuation are great. Moreover, such valuations are those of the moment, during a period when changes are rapid and when there is a wide spread between tax values and holding prices. Neither is it true that, irrespective of the movement of values, their ratios remain unchanged. County sewer districts are generally composed of relatively valuable land which is in immediate and clear need of sanitary improvement, and, further, of acreage which is still under cultivation. The latter is often a large part of the gross area. It is included in the district wisely and (under the present law) in bulk willingly, but the fact remains that its need for service is distinctly of the future. Because of this, there is excellent reason for including valuation or a similar factor as an element of assessment, thus increasing the share to high value lands. However, it is questionable whether, in such cases, values can be estimated to greater precision than with direct evaluation of the resulting benefits.

Table 3 shows derived acreage benefits in a maximum ratio of about 15 to 1 (Areas F5 and A4). This is a greater difference than would result from an apportionment by area, but the writer has spread assessments which have a unit ratio of 12 to 1 without introducing the factor of value.

*Conclusion.*—Mr. Bradbury has based his plan on the thesis that benefits are measured by the increase in value which results from the improvement. This is true, of course; but it is not at all clear that the enhancement is proportionate to the initial value or to any constant factor thereof.

The writer is impressed with the paper as a workable plan that accounts for pertinent elements in a manner which reflects the matured judgment of an engineer who has labored with the problem. However, the theory is not—

and cannot be—provable. Under conditions in which the variables are determinable within reasonable error, this method should yield satisfactory results, but its use should certainly be coupled with experience and caution in fixing futurities as well as present valuations.

The general subject of special assessments offers a splendid field for engineering analysis and economic thought.\* However, a technical passion for precision should not obscure the human elements that are involved.

E. G. BRADBURY,† M. AM. SOC. C. E. (by letter).—The rates charged by the City of Columbus for disposal of sewage from county sewer districts quoted by Mr. Bonney, being based on the number of connections, have the merit of minimizing the necessary accounting between city and county and the work incident to the assessment of the charges against individual property owners. Such rates are not, of course, absolutely equitable but perhaps, on the average, they represent the value of service rendered as correctly as do more complicated methods.

The writer has observed no evidence that unincorporated territory provided with sewer and water improvements is likely to resist annexation to the city. More than one-half the area in which these facilities have been installed by the county has already been annexed to Columbus, and there has been little, if any, opposition by residents or property owners.

The curve for estimating the relation of maximum sewage flow to the average, mentioned by Mr. MacDowell, is also used by the City Engineering Department of Columbus. This fact explains the apparent inconsistency in the statement of Mr. Bonney that the capacities provided by the city are substantially equal to those developed by the basis proposed by the writer, although there is a wide discrepancy between the amounts allowed for infiltration by the two methods. The Morse curve represents the relation of maximum flows to normal quantities in the particular cases observed. The maximum flow is much greater than can be accounted for by fluctuations in the domestic flow and always occurs during or after storms. Therefore, it is evidently due to excessive infiltration or surface water, and is not a function of the domestic flow, as it is made by the use of the curve. It follows that the estimated maximum is unduly affected by the forecast of future population and water consumption. For example, if an area of 100 acres is assumed to have a probable future population of 20 per acre, with a water consumption of 75 gal. per day per capita, and an allowance of 750 gal. per acre per day is made for leakage, the maximum flow as shown by the curve being four times the average, the total quantity per acre is found to be,

$$\begin{aligned} 20 \times 75 &= 1\,500 \text{ (domestic)} \\ 1\,500 + 750 &\text{ (leakage)} = 2\,250 \\ 2\,250 \times 4 &= 9\,000 \text{ gal. per day} \end{aligned}$$

\* An excellent view of current practice in assessing is afforded by bibliographies which are contained in Engineering Societies Library Searches 383, 383a, 2897, and 3555. The Library of Congress also has similar lists. The legal side is covered by the works of Dillon ("Law of Municipal Corporations"), McQuillan (similar title), and, for Ohio, by Page and Jones ("Taxation by Assessment"). Most of the current references bear on assessments for paving.

† County San. Engr., Columbus, Ohio.

After deducting 225% of the domestic flow as a reasonable maximum rate, the actual allowance for infiltration is found to be 5 625 gal. per acre per day.

By the same process, if the population of the district is taken at 30 per acre and the water consumption at 100 gal. per capita per day, and the same figure, 750 gal. per acre per day, used for leakage, it will be found that provision is made for 8 250 gal. per acre per day of infiltration.

If the total normal flow is approximately equal to that on which the curve is based, it will give satisfactory results, but otherwise its use may lead to serious errors. Much of the published information concerning infiltration is misleading because it refers to average leakage rather than to the much higher rate following severe storms. Infiltration is often referred to as being quite constant in quantity, which is far from true. It appears more rational to estimate separately the maximum domestic and infiltration rates, adding for commercial and industrial use when necessary, than to set up an arbitrary relation between average and maximum without consideration of the components.

Mr. MacDowell questions the use of valuation as a factor in apportioning assessments. The writer agrees that this factor cannot be used "with surety that justice is being served," but contends that this is true of any method used, and that justice will be more nearly and more often served if value is taken into consideration than otherwise. The measure of benefit is the enhancement of value of the property. Property located in unfavorable surroundings, and, therefore, low in price, cannot be enhanced in value (in terms of dollars, not in terms of percentage) as much as well-located lots which command prices perhaps several times as great. The use of a factor in direct proportion to value over-emphasizes this condition, but some recognition of relative value is necessary. It is true that a wholly illogical standard of values has been established for platted areas as compared with unplatted land, and owners of the latter may change its status almost over night, thus gaining some advantage over their less astute neighbors. On the other hand, it is to be noted that the owners of platted and developed territory are usually the instigators of the improvement and, in a sense, force it on those whose property is still in acreage and who, for reasons of their own, have not yet seen fit to put it on the market. Among such owners will be found many who are looking forward to later development and others who desire to occupy their land for agricultural or other purposes. There is some justice in placing the greater burden of assessment on those who are asking for the improvement as compared with those who consider it more or less premature in relation to their holdings and accept it only as a necessary evil.

It is desirable that the assessment on the more remote areas, often held in sizable parcels as farm land, be made as low as possible consistent with reasonable equity, and the use of the value factor helps in this direction. There have been several cases in Ohio Courts in which it has been claimed that sewer assessments were confiscatory, and at least two cases in which the Courts have sustained this contention. The writer believes that such

a result will often follow if the valuation factor is eliminated, but can hardly occur if value is properly recognized.

The Missouri Sewer District Law, passed in 1927,\* provides for the levying of taxes in sewer districts, and for re-adjusting the apportionment from time to time as conditions change. This is an interesting development and, unless too cumbersome in operation, may be an improvement over the Ohio method.

Mr. Olson gives a graphic description of conditions where suburban development is not controlled by proper laws and regulations. Similar conditions (perhaps in a lesser degree) were encountered and cured when the Ohio law came into operation. Real estate operators still sometimes prefer to install sewers and water mains in their developments, but under the Ohio law they are required to do such work according to approved plans, and under county supervision and inspection, the owner paying all expense. In Franklin County such owners are further required to convey such sewers and water mains to the county as soon as completed, for a nominal consideration, for the use and benefit of their property; to place in the County Treasury an amount representing the estimated cost of maintenance for one year; and to authorize the county to levy maintenance assessments against the same property as may be necessary in the future. This procedure was adopted after it was learned by experience that such improvements, if left in the hands of the original owner, are usually entirely neglected after the lots have been sold out, no one being responsible for their maintenance and the county having no funds for the purpose, nor any legal right to operate private sewers or water mains.

Mr. Tolles refers to a provision in the Ohio law which authorizes the payment to County Commissioners of fees based on the cost of the work. This section has been held unconstitutional by the Franklin County Courts, the decision being affirmed by the Circuit Court of Appeals, and is, therefore, no longer effective in this Judicial District, which includes several counties in Central Ohio. How this decision affects the remainder of the State has not been determined.

The various uncertainties and difficulties in establishing time and value factors, referred to by Mr. Tolles, must, of course, exist, but the writer has not found them serious. Assumptions are necessary in many classes of engineering work. The fact that one must estimate future population, water consumption, and infiltration does not justify an arbitrary guess at the necessary capacity of a trunk sewer. The same principle may reasonably be applied to the assessment problem. Intelligent forecasting of the various factors, and a logically developed result therefrom, should ordinarily produce the most nearly correct answer to problems of this type.

In conclusion, the desirability of a method of apportioning assessments to the satisfaction of property owners is self-evident. The Franklin County method has the merit of appealing to the general public as fair and equitable; it is capable of quick explanation in simple language; and it provides something more to rely on than mere personal judgment.

Paper No. 1736

### THE PRACTICAL UTILITY OF HIGHWAY TRANSPORT SURVEYS\*

By G. F. SCHLESINGER,† M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. R. H. SIMPSON, W. A. VAN DUZER, N. W.  
DOUGHERTY, W. W. CROSBY, CHARLES RANDOLPH THOMAS, JR., AND G. F.  
SCHLESINGER.

#### SYNOPSIS

This paper describes how the data obtained in a State-wide traffic and transport survey of the State highways of Ohio were utilized in formulating a plan and budget for future highway improvements. The field information was collected and recorded during a period of one year—December, 1924, to December, 1925. The routes of the State system of highways were classified as to traffic importance, based on the following considerations: (1) Density and character of traffic applied, for convenience of analysis, to five sections of the State; (2) maximum concentration periods; (3) influence of truck and bus traffic; (4) influence of population; (5) traffic service afforded by continuous routes and required by the needs of the individual citizen; and (6) the development and growth of future traffic. The plan of improvement was based on the traffic classification and the existing condition of the highways. A budget of the estimated cost to complete the plan in a 5-year period was prepared.

#### PROCEDURE FOR OHIO SURVEY

A highway transport survey is an accurate and comprehensive collection of traffic data, followed by study and analysis. A number of States, cities, and

\* Presented at the meeting of the Highway Division, Columbus, Ohio, October 13, 1927.

† Chf. Engr. and Managing Director, National Paving Brick Mfrs. Assoc., Washington, D. C.

other political subdivisions have carried on so-called traffic surveys with the object of securing information that would be of value in the solution of their highway problems. The Federal Government, through its Bureau of Public Roads, has taken a leading part in similar investigations. Prior to 1924, it had co-operated with the Highway Departments of California, Connecticut, Maine, and Pennsylvania, and also had made an intensive study of traffic in Cook County, Illinois.

A recent project of this kind was a survey of transportation on the State, county, and township road systems of Ohio under a co-operative agreement between the Bureau of Public Roads and the Ohio Department of Highways and Public Works.\* Due to the activities of the Bureau, the methods of making such surveys on rural highways have approached standardization. The Ohio survey was begun in December, 1924, and continued for a period of a year, thus covering all seasonal variations. Data were recorded at 1158 points located so as to obtain the variations in traffic of various routes and sections of routes. Stations were also located on representative secondary county and township roads. At 358 of these points complete data were recorded one day each month during the year period. At the remaining 800 points counts of passenger cars and motor trucks were obtained on three days during the summer months. Data obtained at these stations included a count of passenger cars, motor trucks, motor buses, horse-drawn vehicles, foreign vehicles, and detailed truck and passenger-car statistics. Motor-truck data included the capacity of the truck, State of registration, place of ownership, origin, destination, type of origin and destination, commodity carried, and tire equipment. For alternate periods, at 156 stations, total gross and rear-axle weights were measured by portable scales. Passenger-car data included the State of registration, place of ownership, purpose of trip, origin, destination, and number of passengers.

Each operation consisted of a 10-hour observation period, alternating between 6:00 A. M. to 4:00 P. M. and 10:00 A. M. to 8:00 P. M. Special observers tabulated traffic between 8:00 P. M. and 6:00 A. M. at selected stations, at which, therefore, complete 24-hour observations were obtained. These were made the basis of computation of hourly variations in traffic and of average daily traffic at all stations. Traffic observations for periods of a week were also made at selected stations to determine variations by days. Seasonal changes were computed from the monthly operations at all stations. A carefully planned schedule covered the various days of the week and prevented duplicate recording of traffic.

#### INFORMATION TO BE OBTAINED

The business of highway departments is to produce transportation service for the users of the highways. A successful head of a business must

\* The report of this survey was published in the fall of 1927. The highway traffic studies upon which it is based, were conducted under the joint supervision of Thomas H. MacDonald, Chief of the Bureau of Public Roads, U. S. Department of Agriculture, and the writer, then Director, and L. A. Boulay, former Director of the Ohio State Department of Highways and Public Works. J. Gordon McKay, Chief of the Division of Highway Economics, Bureau of Public Roads, directed the work of the survey and preparation of the report, assisted by Messrs. O. M. Elvehjem, E. T. Stein, L. E. Peabody and B. F. Root, all of the Division of Highway Economics, and Messrs. Harry J. Kirk, Ohio State Highway Engineer, and Harry E. Neal, Ohio Traffic Engineer.

have full knowledge of his market, that is, reliable information as to the demand for his product, its quantity, and location. A highway transport survey is an effort to supply this information to the engineer executive. Such surveys have been criticized on the grounds that highway authorities cannot make practical use of the data obtained; that the survey is interesting as a speculative thesis, but has no utilitarian value. The principal application of the evidence produced is as the basis of a plan of future highway improvement for a period of years. It is logical that such a plan, evolved to meet the requirements of traffic, should be based on the quantity and character of the traffic that it is designed to serve. This type of development from the Ohio survey will be outlined.

The density and character of traffic that existed in 1925 were determined in the field as described. The expected future increase was estimated, and the routes of the State system were classified as to their traffic importance. On this classification was based the plan of improvement for the following 5-year period.

The term, "density of traffic," means the number of motor vehicles passing any given point on a highway in a unit of time. The accuracy of determining it is influenced by the distance between the survey stations. Exactness of method would require a density record for each point on the highway system at which traffic varies. The cost involved, in proportion to the relatively small gain in accuracy, does not justify such a close location of observation points. The density computed for each station on the Ohio Highway System is applied to the short sections of highway that are reasonably adjacent, on which the traffic varies but little.

#### VARIABLE HIGHWAY CONDITIONS

The State highway system of Ohio consists of 11 000 miles of the total of 84 884 miles of rural highways. It is estimated that in 1925 there was a motor-vehicle movement of approximately 3 746 000 000 vehicle-miles on all rural highways and 2 160 000 000 vehicle-miles on the State system. In other words, 13% of the mileage carried 58% of the total motor-vehicle traffic. On the basis of vehicle-miles per mile of highway, the traffic on the State system is more than nine times as intense as that on the secondary rural highways.

The daily volume of traffic on different parts of the State highway system varies widely, as is shown graphically in Fig. 1. Of the 11 000 miles of the State highway system, 131 miles, or 1.2% of the total mileage, carried at the rate of 2 500 or more motor vehicles per day in 1925; 858 miles (7.8% of the system), carried 1 500 or more vehicles per day; 3 239 miles (approximately 30% of the total), carried 600 or more vehicles per day; and 7 761 miles (70.6%), carried less than 600 vehicles per day, of which 4 180 miles carried less than 200 vehicles per day. These relations are shown in Fig. 2.

A basic traffic map of the State was prepared. This is somewhat similar to Fig. 1 and shows the details of distribution of passenger-car and motor-truck traffic, the estimated 1930 traffic, the traffic classification, and the density

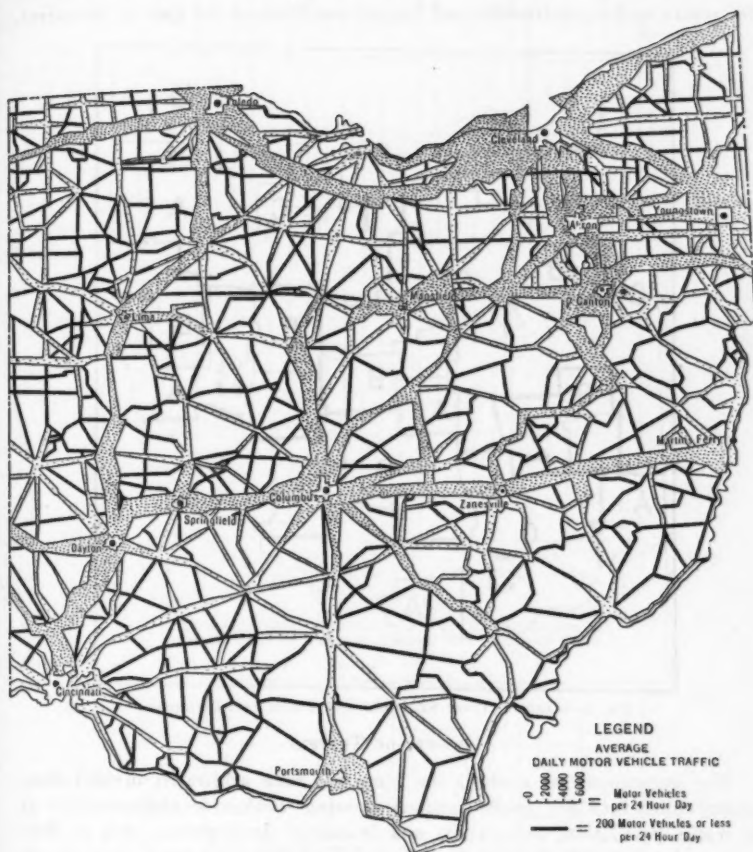

FIG. 1.—MOTOR VEHICLE TRAFFIC ON OHIO HIGHWAY SYSTEM.

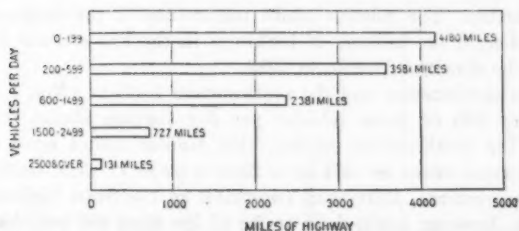

FIG. 2.—MILEAGE OF STATE HIGHWAYS BY TRAFFIC DENSITY CLASSES.

and trend of population by townships. In its preparation, allowance was made for routes under construction and in poor condition at the time of the survey.

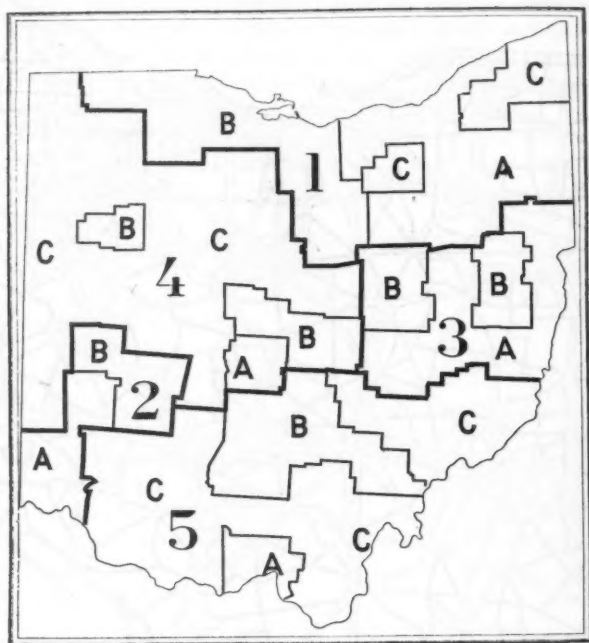

FIG. 3.—OHIO TRAFFIC SECTIONS AND THEIR SUB-DIVISIONS.

#### DENSITY OF TRAFFIC

For convenience of analysis the State has been arbitrarily divided along county lines into five traffic sections showing distinctive characteristics as to traffic, population, topography, and industrial development, each of these sections being subdivided in the order of its traffic importance, into two or more divisions, as shown in Fig. 3, which if compared with Fig. 1 will show the location of the traffic sections with reference to traffic density, population, and industry. The relative traffic importance of the sections is shown in Table 1, wherein the mileage of highways in the five sections is classified according to the density of traffic in 1925.

Within the northeastern and the southwestern sections (Nos. 1 and 5) the routes carrying 600 or more vehicles per day include almost one-half the mileage. In the northwestern section, also, similar routes serve to connect the more important cities, as well as to form a series of short sections radiating from these centers. More than two-thirds of the State highway mileage in this section, however, has a daily traffic of less than 600 vehicles.

In the southern area, sections of highways carrying from 600 to 1500 vehicles per day comprise only 15.0% of the State highway mileage in the area; and this relatively small percentage serves the more important cities.

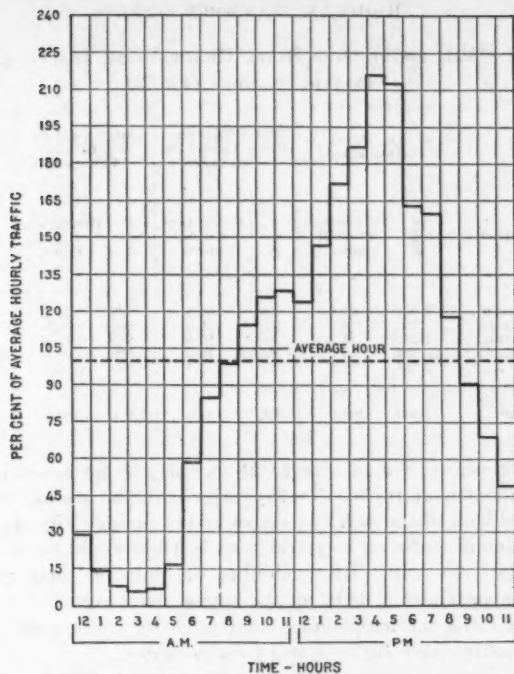

FIG. 4.—HOURLY VARIATION OF TRAFFIC EXPRESSED AS PERCENTAGE OF TRAFFIC DURING THE AVERAGE HOUR.

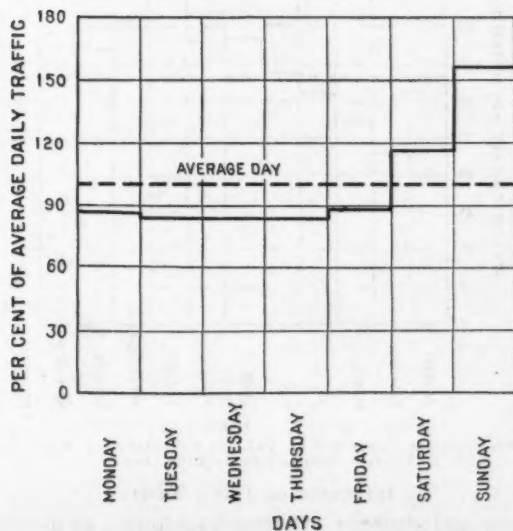

FIG. 5.—DAILY VARIATION OF TRAFFIC EXPRESSED AS PERCENTAGE OF TRAFFIC DURING THE AVERAGE DAY.

The traffic density for an average 24-hour day by no means represents the peak concentration of traffic. Traffic varies with the season, month, day of the week, and hour of the day. As shown by the survey (Figs. 4, 5, and 6) the normal maximum traffic on a typical road in Ohio would occur on a Sunday in August at 4:00 P. M. By combining the data on these graphs this is found to be approximately 480% of the annual daily average. In the vicinity of the larger cities the maximum concentration of traffic necessitates consideration of multiple-lane surfaces and parallel routes.

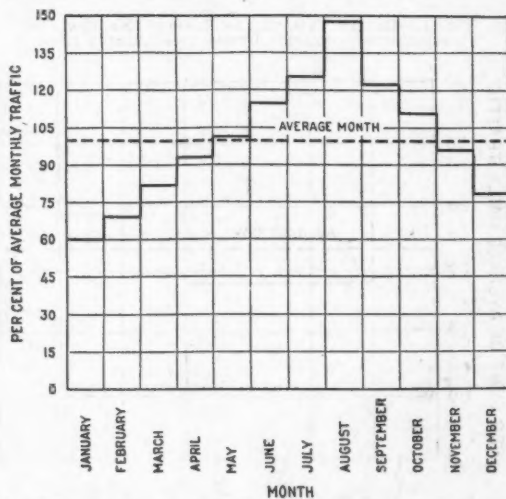

FIG. 6.—MONTHLY VARIATION OF TRAFFIC EXPRESSED AS PERCENTAGE OF TRAFFIC DURING THE AVERAGE MONTH.

#### INFLUENCE OF TRUCK TRAFFIC

The density and character of motor-truck traffic, as distinguished from passenger-car traffic, must be known in the planning of a system as well as

in the design of pavements. It was found to vary greatly on different routes and in various parts of the State. While it averages only 9.5% of the total on the State system, its importance is due to the greater load concentrations, the use of solid tires (15% of all trucks), and a lack of refinement in springs and shock-absorbing parts.

The relative importance of the five traffic sections from the standpoint of truck traffic is shown in Table 2 and Fig. 7. The influence of large cities on density of truck traffic is shown in the two most important trucking areas, the northeastern and southwestern sections, which have five of the seven cities between 30 000 and 100 000 population.

\* U. S. Census of 1920.

It was found that the rated capacity of trucks was a reliable criterion of the weight of the total gross load, and that the proportion of the total gross load on the rear axle increases with an increase in capacity of the truck.

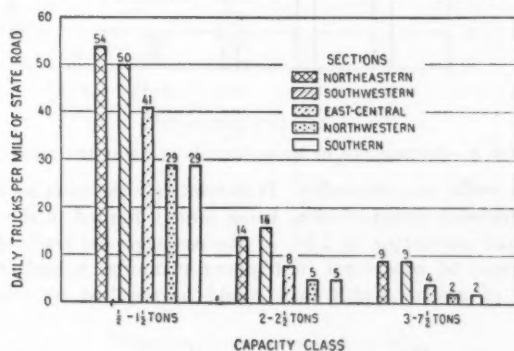

FIG. 7.—DISTRIBUTION OF MOTOR TRUCKS BY CAPACITY CLASSES IN THE FIVE TRAFFIC SECTIONS OF OHIO.

The highway engineer, therefore, must provide for increased load concentrations on routes where large capacity truck traffic is a factor. Only about 2.1% of the trucks with a rated capacity greater than 5 tons were operating

on the highways (see Fig. 8). This was evidently due to Ohio's legal maximum gross load limitation of 20 000 lb. (10 tons). It is also in line with the general tendency to prefer medium-sized units as the highway transportation vehicle. It was found that, in general, the heavier gross loads occurred on routes carrying a high density of truck traffic, although there were exceptions to this general rule accounted for largely by special movements, such as the hauling of gravel, sand, and stone for construction work.

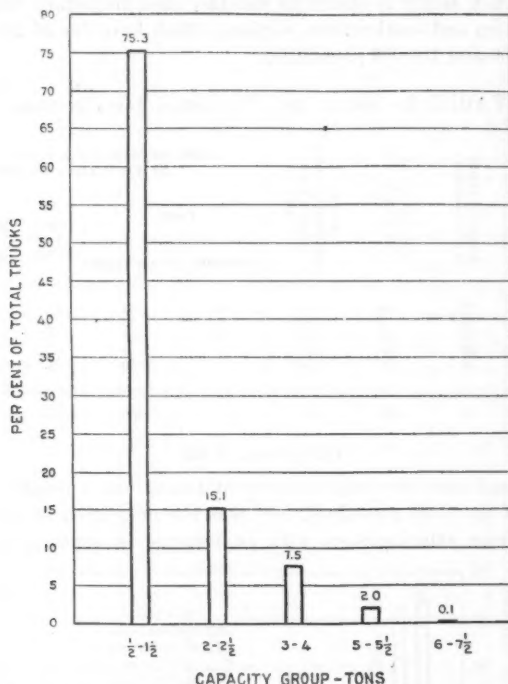

FIG. 8.—DISTRIBUTION OF MOTOR TRUCKS BY CAPACITY GROUPS.

Motor-bus traffic was noticeable. It is relatively the most rapidly increasing type of highway transportation, being largely limited to the State highway system and amounting to 1.5% of the passenger-car traffic during 1925. This traffic must be considered in highway planning, necessitating a high type surface of greater width than would be required by other types of traffic.

#### HIGHWAY TRAFFIC AND POPULATION

The volume of highway traffic in an area is largely a function of the population of the area. A study of traffic and population shows, that the concentration of traffic is greatest in the areas tributary to the large cities of the State.

Analysis of the trip-mileage of motor vehicles in Ohio shows that 60.4% of the cars observed, travel less than 30 miles per trip, and approximately 70.0%, less than 50 miles; also, that 71.6% of the trucks travel less than 30 miles, and only 14.0%, more than 50 miles per trip. Highway traffic is, therefore, primarily a method of local transportation.

\* Based on estimated population, 1925.

A comparison of the factors producing traffic in the five traffic sections is shown in Table 3. The three divisions having the greatest density of population also have the greatest volume of traffic per square mile, but the traffic on the State system is not in the same ratio to population or motor-vehicle

registration as in the other sections. This variation is due principally to the following causes:

(1) In the populous sections a larger proportion of the traffic is on city streets instead of on State highways.

(2) In the populous sections the roads other than those on the State system carry a greater proportion of the traffic.

(3) Traffic originating in the populous sections uses highways in other sections to a greater extent.

A county or area should not be required to bear a major portion of the financing of the improvement of a through route for the benefit of traffic that is not of local origin. The distribution of population affects the planning of highway improvements in several important particulars. Densely populated areas require pavements of a width and type that will serve adequately and expeditiously the large volume of traffic, including trucks and buses; between important centers of population. On such routes, separation of grades at railroad crossings, reduction of heavy grades, revision of poor alignment, elimination of curves around parks in small villages, construction of multiple-lane and parted pavements, and the avoidance of traffic deterrents in general are economically justifiable. An adequate plan of highway facilities in such areas requires the provision of "by-pass" routes around cities, which not only are of benefit to traffic on the main routes, but also decrease traffic on the city streets by drivers unacquainted with local conditions.

Although a rigid application of the evidence does not justify the inclusion of as large a mileage of through highways in the less populated sections, the principle of traffic service makes a connected system of routes in such areas a proper function of the State. As shown in Table 3, the vehicle-miles on the State system per person and per motor vehicle in such areas are greater. It would follow, therefore, that the State routes are of greater service to each individual resident of these sections. It is true, however, that highways of width in excess of a normal two-lane road are rarely required and low-type surfaces of the traffic-bound type will give ample service for years in the future.

#### FORECAST OF FUTURE TRAFFIC

Any sound plan for highway improvement should take into consideration the traffic of the future in so far as it can be predicted with reasonable accuracy. Ohio had no historical series of traffic counts previous to 1925. From a study of such records of varying length and accuracy, from Maine, Maryland, Massachusetts, Michigan, and Wisconsin, it is evident that in these States, highway traffic has increased directly with the increase in motor-vehicle registration. This assumption was adopted for the Ohio forecast. The registration for a 10-year period until 1935 was estimated by computing future population, using the Bureau of Census method and by extending the persons-per-car curve, the former, of course, having an upward and the latter, a downward trend. By combining the estimated population and the estimated number of persons per car the predicted registration for each year is obtained. The results are shown in Table 4.

In forecasting traffic in 1930 at each traffic station, the procedure was similar to that for predicting motor-vehicle registration in each county, the county rate being applied to each traffic station in the county. For a number of reasons such refinement was not considered justifiable in the forecast for 1935 which was computed on the basis of the State increase in registration rather than on that of the increase in each county.

The methods described will not reflect certain changes in suburban and industrial growth that may occur and influence traffic on short sections of highways. There are other conditions that cannot be anticipated and taken into account. The Ohio Department of Highways is continuing the traffic survey with a skeleton organization, that is, gathering data at certain key stations of the original survey. This work was inaugurated in December, 1926, two years after the original survey was begun.

#### TRAFFIC CLASSIFICATION OF STATE HIGHWAYS

Having determined the present and future traffic on the State system of highways the next step in formulating a plan of highway improvement was to classify the routes as to their traffic importance. A highway should be designed and constructed so that it will economically serve present and future traffic. The principle of stage, or progressive, construction contemplates the improvement of the roadway with a surfacing that will be increased in strength as the traffic grows. Such a policy has been resorted to—and justifiably so—by highway authorities when funds were not available at the outset for the construction of a durable type of pavement. However, in order that the highways included in a proposed program may be neither over-designed nor under-designed, they should be divided into traffic groups.

The State highways of Ohio are classified in three groups designated as major, medium, and minor, according to their average daily traffic. High-

ways classed as "major" include, in addition to the roads carrying 1 500 or more vehicles in 1925, those sections which carried less than 1 500 in 1925, but which are expected to carry 1 500 or more vehicles in 1930; similarly, in 1930, in addition to the sections actually carrying at that time 1 500 or more vehicles there are included as major traffic highways those which are expected to carry that number in 1935.

A similar method is utilized in classifying the highways of the medium traffic group, which includes sections actually carrying between 600 and 1 500 vehicles per day in 1925 and expected to carry that number in 1930. Minor traffic highways, on the other hand, are those which are expected to carry less than 600 daily vehicles in 1925 and 1930.

The traffic limits selected are in line with general highway engineering practice and were confirmed by a study of maintenance costs on various types of surfacing in Ohio. A traffic density of 600 vehicles per day is the limit at which traffic-bound gravel or stone roads can be economically maintained. For greater intensities this type should be strengthened with bituminous treatment or additional courses. A traffic density greater than 1 500 vehicles per day calls for a standard pavement design—the flexible or rigid types for the lower densities, and usually rigid pavements only for roads carrying large volumes of traffic with the accompanying frequency of heavy loads.

The mileage of major and medium classification in 1930 which is not now improved with surfaces superior to gravel affords a reliable index to the need for new improvements during the next few years. The quantities shown in Table 5 include all highways now having such surfaces, regardless of condition or present width. Included in this mileage is a considerable length in poor condition which must be reconstructed to provide adequate highway service, and a large mileage of narrow surfaces which must be widened in order to serve present and expected future traffic.

TABLE 5.—MILEAGE OF SURFACES SUPERIOR TO GRAVEL IN 1925 AND 1930.

Section.	Mileage of major and medium classification, 1930.	Mileage of major and medium classification improved with surfaces superior to gravel, 1925.	Mileage of major and medium classification not improved with surfaces superior to gravel, 1925.
Northeastern.....	1 985	1 160	825
Southwestern.....	469	282	187
East-central.....	547	323	224
Northwestern.....	1 370	620	750
Southern.....	850	303	547
Total.....	5 221	2 688	2 533

In the east-central, northwestern, and southern sections more than one-half the total State highway mileage is expected to remain in the minor traffic class in 1935.

#### THE OHIO IMPROVEMENT PLAN

Having determined a traffic classification of the highways on the State system considering traffic needs of the future, the plan of improvement was

formulated based on the existing condition of the highways. The mileage of proposed new construction, reconstruction, and widening in the five traffic sections is shown in Table 6. In the improvement plan for a 5-year period from January 1, 1927, to December 31, 1931 (Table 7), new construction is defined as construction on present unimproved sections of highways and sections where the surface cannot be salvaged because of its condition, location, or alignment. The selection of surfaces for this new construction will be based on traffic and physical conditions. Reconstruction is defined as the rebuilding of worn-out surfaces with the same or a superior surface type. On the other hand, widening is the extension of present surfaces to a minimum of 18 ft. and to a greater width where required. In general, surfaces 16 to 18 ft. in width on minor traffic routes are not included in the widening program. If the condition of the surface requires reconstruction such roads have been included in the reconstruction program. The distinction between widening and reconstruction is not clear in many cases, but for the larger part of the reconstruction mileage the condition of the surfaces is such as to require rebuilding. Where the surfaces are narrow, reconstruction also will include widening of the surface.

TABLE 6.—PROPOSED IMPROVEMENT PROGRAM.

Section.	Total State highway mileage.	TOTAL IMPROVEMENT PROGRAM.		NEW CONSTRUCTION.				RECONSTRUCTION.		WIDENING.	
				Surfaces Superior to Gravel.		Traffic Bound.					
		Miles.	Percentage of total miles.	Miles.	Percentage of total miles.	Miles.	Percentage of total miles.	Miles.	Percentage of total miles.	Miles.	Percentage of total miles.
Northeastern .....	2 821	1 511	53.6	295	10.5	167	5.9	496	17.6	553	19.6
Southwestern .....	736	269	36.6	53	7.2	...	...	88	12.0	128	17.4
East-central .....	1 285	574	44.7	122	9.5	124	9.6	132	10.3	196	15.3
Northwestern .....	3 402	1 360	40.0	252	7.4	332	9.8	306	9.0	470	13.8
Southern .....	2 756	807	29.3	285	10.3	77	2.8	198	7.2	247	9.0
Total .....	11 000	4 521	41.1	1 007	9.1	700	6.4	1 220	11.1	1 594	14.5

The cost of each of the three classes of improvement was obtained by estimating the changes for grading, minor structures, and the approximate surface type required for the sub-grade conditions and estimated future traffic. Exclusive of bridges and the separation of railroad grade crossings, this will amount to approximately \$100 000 000.

The urgent need for widening of present surfaces is indicated by the fact that there were on the State system, in 1925, approximately 4 800 miles of surfaces superior to gravel and less than 18 ft. in width, approximately 1 400 miles being from 10 to 15 ft. wide. On light traffic routes, where the present width is between 16 and 18 ft. and the surface is in good condition, widening can well be deferred to a later period and, therefore, this mileage is not

included in the program. The plan also includes a limited mileage of present 18-ft. pavements, which require additional width to serve existing and expected traffic.

TABLE 7.—PROPOSED OHIO FIVE-YEAR NEW CONSTRUCTION, RECONSTRUCTION, AND WIDENING PROGRAM AND ESTIMATED IMPROVEMENT COST.

Class of improvement.	Miles.	Percentage.	Estimated cost.	Percentage.
New construction.....	1 707	37.8	\$41 122 000	41.2
Surfaces superior to gravel.....	1 007	....	\$34 443 000	....
Traffic-bound .....	700	....	6 679 000	....
Reconstruction .....	1 220	27.0	35 188 000	35.3
Widening.....	1 594	35.2	23 644 000	23.6
Total.....	4 521	100.0	\$99 954 000	100.0

The 5-year new construction, reconstruction, and widening program involves 41.1% of the total State highway mileage. The remaining 58.9% (6,479 miles) consists of surfaces in satisfactory condition and adequate for expected traffic during the next five years.

TABLE 8.—ESTIMATED BUDGET, OHIO STATE HIGHWAY SYSTEM, JANUARY 1, 1927, TO DECEMBER 31, 1931.

Item.	Estimated total cost.	Funds required by State Highway Department.
New construction, reconstruction, and widening of highway surfaces.....	\$100 000 000	\$100 000 000
Bridge construction.....	8 000 000	8 000 000
Railway grade-crossing elimination.....	16 000 000*	8 000 000
Maintenance and repair.....	53 000 000	53 000 000
Administration.....	3 000 000	3 000 000
Contingency fund.....	5 000 000	5 000 000
Total.....	\$185 000 000	\$177 000 000

\* To be shared equally by the State and railroad companies involved.

The reconstruction and widening program is largest in the heavy traffic sections which contain the greatest amount of major traffic mileage. The proposed program for new construction superior to gravel is relatively large in the southern, or lowest traffic, section because of the present small mileage of such types, and it is limited mostly to a few important traffic routes.

An estimate of budget requirements for the 5-year period is shown in Table 8. The estimate given in Table 7 did not include such items as the cost of major bridges, railroad grade-crossing eliminations, routine maintenance, contingencies, and administration. The elimination of grade crossings presents a serious problem when it is considered that there are more than 1 000 railroad crossings at grade, outside of cities, on the State system.

## CONCLUSION

An endeavor has been made in this paper to describe how the results of a transport survey have been utilized, in a practical manner, by establishing a plan of State highway improvement for a period of years, and preparing a budget required by this plan. Other information made available by a transport survey is useful in many ways, but might be classified as being outside the scope of practicality. For example, in the Ohio survey the composition of passenger-car traffic as to state of registration, touring or non-touring, business or non-business, city or farm ownership, was obtained. The fact that the survey evidence indicated that 87.6% of the passenger-car traffic on the State system was of city ownership had a decided influence on the type of measures adopted by the Legislature of 1926-27 for financing improvements on the State highway system. Other information obtained included such data as: Average mileage per trip for passenger cars and trucks; average number of passengers per car; trucks for hire and privately operated; principal commodities hauled by commercial trucks; classification of commercial and private trucks according to capacity; and a comparison of motor truck and railroad tonnage between selected Ohio cities.

The results of the survey and the plan based thereon were presented to the 1927 General Assembly and were effective in obtaining sizable appropriations for State highway improvements, although not quite as large as called for by the budget (Table 8). The main benefit to be expected from the establishment of the plan is that the Ohio Highway Department now (1927) has a definite aim toward which it can direct its future efforts. The fact that the Federal Highway Bureau was a party to its formulation, and that it has been endorsed by the non-political organizations of the State interested in highway progress and the highway industry, would seem to insure its inviolability as the future road program for Ohio.

## DISCUSSION

R. H. SIMPSON,\* M. Am. Soc. C. E.—The author has shown very clearly that a knowledge of how the highways are used is just as essential to the man who directs the activities and policies of a highway system, as a knowledge of the market for a commodity is to a business executive. Engineers have devoted much time and study to the details of pavement construction, and yet it is only recently that they have made an effort to find out the use and abuse to which roads and streets are subjected.

In the design of a bridge, careful consideration is given to the loads to be sustained. Is it not important, therefore, to know the character and density of traffic to be carried in order to decide the type and to construct a pavement properly? A lack of such information in past years has not only led to the selection of types entirely inadequate to handle the volume of traffic carried, but in some cases to the selection and construction of types, the cost of which cannot be justified by traffic conditions. Engineers are beginning to recognize, however, that a knowledge of present, and an intelligent forecast of future, traffic is essential, if they are to design properly and to construct roads and pavements economically.

Since a large percentage of the traffic on the main highways of the State originates in the cities, it will be of interest to know something of the movement of traffic in the City of Columbus, Ohio. The Ohio survey shows that approximately one-eighth of the rural roads carries more than one-half of the total road traffic. What percentage of city traffic is carried by the main thoroughfares within that city? What is the relation of traffic to the paved mileage in a city; what is its intensity; its fluctuations, and its character? It may not be necessary to know the seasonal variation, but it is desirable to know the direction and maximum intensity of traffic in order to plan intelligently the development of a city. The general direction of traffic will indicate clearly the need of widening present thoroughfares, and will show where additional arteries of traffic may be required.

To obtain a complete and accurate record of the flow of vehicular traffic over the streets of a city presents a problem of some difficulty. It is manifestly impractical to secure information as to ownership, origin, and destination of traffic on a thoroughfare carrying 1 000 vehicles per hour, and such information is hardly necessary in solving problems arising from city traffic. This special problem is rather one of density and calls for information as to direction, total volume, maximum intensity, and something as to the character of traffic.

Traffic counts at best give only an indication of traffic movement within reasonable variation. A count to-day will not agree with one to-morrow or yesterday. The density of traffic at a particular point will vary with the seasons and with weather conditions. It will vary with the day of the week and the hours of the day. Notwithstanding the inexactness of the data, a survey of traffic is very important for the engineer who must plan a system of highways as well as those who must solve the traffic problems in cities.

\* Chf. Engr., Dept. of Public Service, Columbus, Ohio.

A few isolated traffic counts were made in Columbus about 1924, but the first systematic survey was undertaken in 1925. The data obtained from this effort, while not very complete, convinced the speaker of the need of continuing the work during the following year. In 1926 a more complete and thorough survey was attempted. The work was under the direction of R. C. Chaney, M. Am. Soc. C. E., Engineer for the City Planning Commission. It was begun on June 14 and continued daily, except Sunday, until September 28. The standard forms prepared for this work enabled the observer to record all traffic movement at a station, so that the movements of any 15-min. interval would be known. Most of the stations were at street intersections, so that the record would show the movement straight through on each street and the right and left turns. The data noted included a count of passenger cars, light and heavy trucks, and horse-drawn vehicles. Data were obtained at 210 stations selected to cover the entire city. The observation period was from 6:00 A. M. to 10:00 P. M. Some Sunday counts were taken at a few stations. At a number of selected stations a complete 24-hour count was taken, and, at a few, the movement was observed for seven consecutive days. Many of the stations were handled by a single observer, but on heavily traveled thoroughfares, two observers worked together.

While the survey covered a 16-hour day, a 13-hour day was adopted for the purpose of this study, from 6:00 A. M. to 7:00 P. M., as a standard interval best suited to give a dependable average traffic. This period covers the business day, both commercial and commuting, and the traffic during this interval is fairly uniform throughout the year. The traffic for this interval is about 70% of the 24-hour traffic.

There are in Columbus about 540 miles of dedicated streets. Of this total, 400 miles are improved. The remainder of the mileage is not improved, so that practically all the traffic movement of the city is carried by the 400 miles of improved streets. The roadways vary in width from a minimum of 18 ft. to a maximum of 80 ft., the average being about 30 ft.

Of this paved mileage, 48.12 miles, or 12.03%, may be classed as main thoroughfares, arteries that lead from the center of the business district in all directions to the suburban sections; 38.25 miles, or 9.56%, may be classed as secondary thoroughfares; and 313.62 miles, or 78.41%, as minor streets. The average daily movement (13-hour interval) on these roadways is as follows:

Main thoroughfares.....	7 000 vehicles, or 336 875 car-miles
Secondary thoroughfares..	3 434 vehicles, or 131 370 car-miles
Minor streets.....	410 vehicles, or 125 450 car-miles

---

Total daily movement.....	593 695 car-miles
---------------------------	-------------------

This equals a movement of about  $9\frac{1}{2}$  miles per day for each registered car in the city.

It is interesting to note that the main and secondary thoroughfares, representing 21.59% of the paved mileage, carry 81% of the traffic movement. It will be noted, also, that the main thoroughfares, representing 12.03% of the paved mileage, carry 56.7% of the traffic movement. This fact is rather striking in that it agrees closely with figures presented by Mr. Schlesinger on

the relation of traffic on the State routes as compared with the total rural traffic movement. In other words, the traffic movement on the main thoroughfares of the city bears about the same relation to the total traffic in the city streets as the traffic on the State routes bears to the total rural traffic.

The character of the traffic on city streets is of some importance. The Columbus survey shows that an average of 16% of the vehicular movement is motor trucks, and that approximately 25% of these trucks were classified as heavy, so that about 4% of the traffic consists of heavy trucking units. The movement of horse-drawn vehicles is negligible because less than 1% of the traffic is of this class.

Figs. 9 and 10 show the variation of traffic in the city compared with that of the State highways, the data on the latter being from the Ohio survey as presented in Fig. 6 by Mr. Schlesinger. Fig. 9 shows the hourly variation expressed as the percentage of traffic during the average hour. It will be noted that the intensity of highway traffic increases rather uniformly from a minimum at 4:00 A. M. to a maximum at 4:00 P. M. The traffic intensity in the city, however, while rising rapidly in the morning, is fairly uniform from 8:00 A. M. to 4:00 P. M. The maximum intensity occurs about 6:00 P. M., followed by a slump with another peak in the early evening.

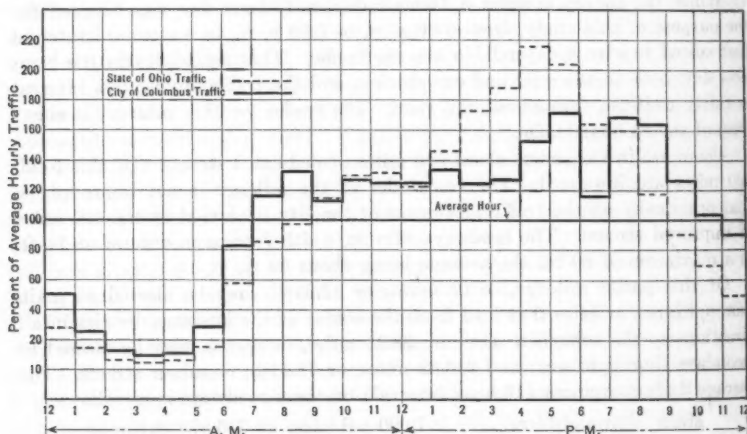

FIG. 9.—HOURLY VARIATION OF TRAFFIC EXPRESSED AS PERCENTAGE OF TRAFFIC DURING THE AVERAGE HOUR.

Fig. 10 shows the daily variation of traffic expressed as percentage of traffic during the average day. The traffic intensity on the highways reaches a maximum on Sunday, while in the city it is a minimum on that day. On the highways, the Saturday and Sunday traffic is more than the average and, in the city, the traffic intensity exceeds the average on Monday and Saturday.

Studies in Columbus have not been carried to a point where a complete thoroughfare plan can be outlined for the needs of the city, but in a number of locations it has furnished evidence to show the need of wider roadways and new thoroughfares. The traffic survey has been an aid in determining the

proper location and the proper width of arteries extending into newly developed territory and in planning the development of suburban areas. It has also furnished evidence to aid in the selection of locations for the installation of automatic traffic signals.

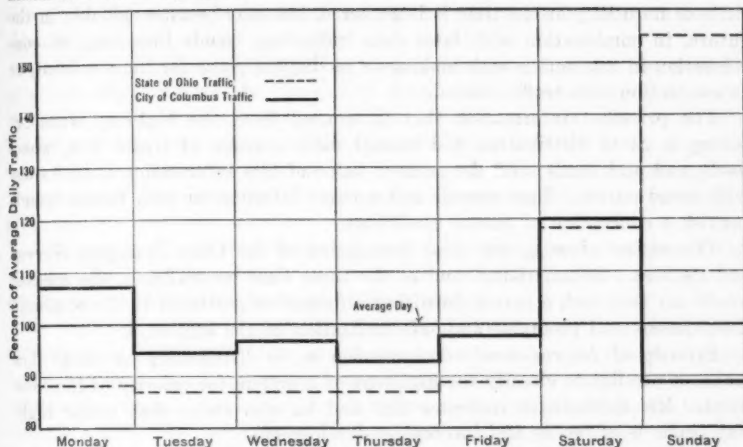

FIG. 10.—DAILY VARIATION OF TRAFFIC EXPRESSED AS PERCENTAGE OF TRAFFIC DURING THE AVERAGE DAY.

The traffic on the streets should also be studied in an effort to determine its effect on pavements. What is the relation of traffic to the wear and repair of pavements? A few years ago this question was of little moment, but the use of self-propelled vehicles has reached such proportions as to show its effect on pavement surfaces. To-day, many hard-surface pavements which carry a large volume of traffic are showing abrasive wear, especially where the traffic is concentrated in narrow lanes and has no opportunity to spread over a wide area. A test of a concrete pavement by the U. S. Bureau of Public Roads, at Arlington, Va., showed an abrasion under concentrated traffic of nearly 0.01 in. by the passage of a vehicle 55 000 times over the surface. At the same ratio 1 000 000 vehicles would have resulted in a wear of 0.17 in. Some observations by the speaker on a pavement in Columbus, carrying 5 000 000 vehicles yearly, shows that rubber-tired traffic will abrade hard surfaces, and there is evidence to show that the abrasion is approximately proportional to the volume of traffic. When it is realized that many pavements carry a traffic in excess of 2 000 000 vehicles yearly, it is clear why many of them are showing signs of distress, and why such vast sums are required for maintenance. Is it not important, therefore, to have a knowledge of the traffic conditions in order not only to plan the future development of rural and urban communities intelligently, but to design and construct pavements properly? The time is past when pavements should be constructed without reference to the use to which they are to be placed. The engineer should know within reasonable limits the density and character of the traffic to be carried. The only way to secure this information is by a traffic and transport survey.

W. A. VAN DUZER,\* M. AM. SOC. C. E.—As Mr. Schlesinger states, the principal application of evidence produced from highway transport surveys is as bases of plans for future highway improvement. Furthermore, the value of a transport survey is cumulative. A great deal of the evidence may be of little or no utility at the time it is gathered, but may become valuable in the future, in combination with later data indicating trends important of consideration in connection with making or modifying plans for improvement, or in connection with traffic control.

The principal information that is secured from the highway transport survey is as to distribution and annual daily average of traffic flow, wheel loads, and peak loads; and the greatest value of this information is in its use with trend curves. Past records and present information with future trends furnish a conception of future conditions.

The author gives a very clear description of the Ohio Transport Survey and its uses. Summarizing, and at the same time generalizing, the speaker would say that such a survey furnishes information pertinent to the economic development and profitable and safe utilization of the highways.

*Priority of Improvement.*—Information as to distribution of traffic flow makes it possible to classify the highways of a system for priority of improvement. Mr. Schlesinger indicates this and he also states that motor highway traffic is of recent and incomplete development.

In twenty years, highway traffic has changed from horse-drawn to motor-driven and in volume has probably increased fivefold. Since 1908 the necessity for greater strength and durability has increased the cost per mile of pavement construction approximately five times, while the demand for more mileage has increased in even greater proportion.

At present (1927), the pressing task is to provide a durable, hard surface on a vast mileage of trunk highway systems, and the highway transport survey may be considered as furnishing data for use in solving the problem of priority of improvement.

In general, the total volume of traffic, as, for instance, when expressed in total vehicle-miles, is a measure of the value of road service. In order to determine the merit or efficiency of any road system, it is necessary that its value to the user—which may be considered as the saving in operating over improved, rather than unimproved, roads—be capable of comparison with the cost of furnishing improved roads.

As an illustration, it is estimated that total travel on the Pennsylvania State Highway System in the next four years will average about 10 000 000 000 vehicle-miles per year; that there is a 25% saving in operating over improved road, equivalent to 2½ cents per mile for passenger-car travel and 9 cents per mile for motor trucks and buses. Assuming 10% motor-truck and bus traffic, the annual saving is about \$225 000 000 for passenger cars and \$90 000 000 for motor trucks and motor buses, or a total of \$315 000 000 per year for all traffic. It is very important that the capital charges plus upkeep of the State highway investment show a profit to the public. Admittedly, estimated unit savings are open to question; but the figures appear to be reasonable, and until

\* Deputy Eng. Executive, State Dept. of Highways, Harrisburg, Pa.

the road costs approach such total as would be equivalent to savings computed by using such lower savings figures as might be advanced, the question as to accuracy of the estimate is not critical. The more definite determination of savings figures, however, may prove important in the future and it is through traffic surveys and studies that the improvements in accuracy can be obtained.

*Location.*—The improvement of any route, or any section of a route, raises questions which can only be disposed of satisfactorily by comparison of costs. If, for example, there are two alternative locations, one of which will cost \$30 000 per mile for grading and the other \$20 000, and if the larger expenditures result in a shortening of distance or a reduction of maximum grade, the number of vehicles using the road will determine which of the two is the preferable and economic location.

*Selection of Type.*—The information as to distribution and annual daily average (Table 1) is valuable in the solution of the problems of highway economics in determining the type of improvement.

It is an engineering precept that there should be an estimate of load to be carried, by any structure, throughout its economic life. In the past years traffic has been changing at such rapid rate—while adequate standards of construction were being developed—that forecasting has been virtually impossible; but now that the rate of increase has moderated, a curve of future traffic can be drawn with some logical basis. There are now modern types of pavement which have been carrying traffic a sufficient length of time to warrant estimating the length of their economic life. The relation between volume and weight of traffic, and costs of construction and maintenance of pavement, has become sufficiently stabilized so that it can be observed and studied to verify or correct the assumptions on which the present huge expenditures on highways are based and on which in the future greater expenditures are to be planned.

*Design of Pavement Section.*—Information as to weight of heavy wheel loads and their frequency makes it possible to provide a pavement section of sufficient strength to withstand—without destructive cracking—the loads to which it will be subjected. Conversely, information as to what wheel loads are being carried without serious damage, and what wheel loads are excessive for various types of pavement, will furnish evidence to verify or correct present ideas concerning requirements of cross-section and materials.

Information as to volume and nature of peak loads to be carried and capacity of multiple-lane or parallel roads, under traffic characteristic of locality, is also essential for planning, intelligently, the width of road surfaces. There may not be general agreement as to what should be considered the maximum carrying capacity of two, three, or four-lane roads, under different conditions. It is within the last few years, and only in a comparatively limited mileage, that carrying capacity of two-lane roads has been exceeded, and even now the composition of traffic is still changing. There is, as yet, a wide variation in proportions of motor-truck and bus traffic to be considered in the present as well as estimated in the future. These considera-

tions, however, emphasize rather than detract from the importance of traffic survey data in connection with the planning of improvements.

*Time Factor.*—The principal features of the highway transport survey have been considered to be those which most directly affect the road itself. This has been the point of view necessarily taken during the early stages of development of the road system. With the road system approaching completion, the point of view changes to embrace operation as well as construction. In the future, highway administration may be expected to concern itself more and more with operation and traffic control.

Time is an ever-increasingly important factor. Pavements might withstand the full weight of traffic and carry the full volume of it and yet be unsatisfactory if travel entailed loss of time. It is necessary to provide highway facilities for fast as well as slow travel, as in the case of railroads. In the near future, widening of roads with special lanes for slow travel, or segregation of slow travel to parallel roads, for the purpose of reducing congestion, is likely to occasion large expenditures and, in such cases, adequate information will be required.

With the understanding that road design is to permit occasional over-loads, in the same way that storm sewers are designed to be occasionally overtaxed, the peak load of traffic, expressed in hourly rate, rather than annual daily average, should be the measure of highway capacity. The planning of multiple lanes and parallel roads will be influenced accordingly. Width of right of way as well as width of pavement is involved.

In many cases, especially on trunk roads entering cities where it may not be possible to provide either extra width or parallel roads, unsatisfactory conditions may be remedied by eliminating or reducing to a minimum those features which retard the flow of traffic and constrain the volume-carrying capacity of the road. Such features, concerning which a traffic survey may furnish very valuable information, are railroad crossings, cross-road or side-road intersections, sharp curves, and steep grades.

TABLE 9.—1926 STATE HIGHWAY ACCIDENT HAZARD BY DAY OF WEEK.

Thursday.....	12	12.1	99	136
Friday.....	12	12.8	94	129
Saturday.....	19	15.6	122	167
Total.....	100	100.0	....	....

*Safety.*—The purpose of the highways is their safe and profitable use. Safety requires, essentially, jurisdiction over drivers and minimum specifications, particularly as to brakes and lights. The growing accident loss is to be checked and the proper use of the highways is to be encouraged. This feature

of highway traffic study must receive a great deal more consideration in the future and traffic-flow data must be combined with accident-occurrence data to furnish an accurate conception of the problem which is prerequisite to remedy.

Table 9 furnishes an example. It shows that in 1926, of accidents reported as occurring on the State highways of Pennsylvania, the percentage charged to Sunday was greater than that for any other day of the week, but when daily average of traffic is taken into account, it is found that Sunday is the day of lowest relative hazard. In connection with the analysis of accident data, it is obvious that the number of accidents is significant and important, but it is also obvious that comparison is valuable; and in this case a comprehensive comparison must include the indication of accident rate in terms of total volume of traffic. Public welfare requires traffic control, and traffic control necessitates traffic information.

N. W. DOUGHERTY,\* M. A. M. Soc. C. E. (by letter).—Highway transport surveys, as described by the author, have a special value in connection with the construction of highway bridges that are to be financed by toll charges. In 1927, the State Legislature of Tennessee authorized the construction of sixteen toll bridges. The legislation comprises three acts, each providing for a series of bridges to be considered as a unit and to be financed by the issuance of bonds, which, in turn, are to be retired by the income from tolls.

The bridges in the first group are needed and the tolls will easily finance their construction and maintenance. The bridges of the second group are in isolated areas and on secondary highways and it is doubtful whether any of them will prove to be paying investments. As a whole, this series will be difficult to finance from the tolls collected. The acts authorizing these two groups also fixed the charges that will be made, thus fixing the income which the Highway Department may reasonably expect from the structures. Had studies of income been made before the legislation was enacted, several of the structures would not have been authorized because it would be cheaper to operate ferries without charge. The bridges of the third series will serve a real traffic need and at least two of them will finance themselves. It is probable that the two profitable bridges will finance the third.

All the bridges in each group were classed together, and were to be paid for out of the tolls, the group to be made free as soon as the bonds on the whole series were retired.

*Estimate of Traffic.*—The State Highway Department of Tennessee has been conducting studies for a period of years in order to determine the relation between the average flow and the seasonal flow of traffic as well as the volume of traffic that may be reasonably expected over the proposed bridges. The data show that the traffic in August is approximately 33% more than the average for the year. The total 24-hour traffic is 133% of the daylight flow. This was determined by taking night counts. A 12-hour count taken in August, therefore, approximates the average 24-hour flow throughout the year.

\* Prof., Civ. Eng., Univ. of Tennessee, Knoxville, Tenn.

In 1926 a general count was made throughout the State, and this is used as a basis for predicting future travel.

In Tennessee, as in other States, the increase in traffic flow has been approximately proportional to that of motor-vehicle registration. This has been used as a basis of foretelling the volume of future traffic. Predictions made about 1923 have agreed fairly well with the actual registration for 1926 and 1927.

A more accurate value may be determined if the many sources are estimated separately. A study of vehicle license numbers from the several sections of the State has shown that the preponderance of travel is from the county in which the road is located or from the adjoining counties. The study was divided, therefore, into: (a) Local travel; (b) travel from counties of large registration; (c) travel from other counties of the State; and (d) travel from other States. No effort is made to separate the truck flow from the travel of automobiles, on the assumption that the same law applies for the trucks as for the passenger car.

*Local Travel.*—To estimate local travel, a large number of stations were selected at which the flow of vehicles was obstructed as little as possible. It is well known that detours, bad stretches of road, construction under way, and other obstructions, limit the free flow of vehicles. From preceding counts an estimate was made of the flow of local vehicles at the stations. From records of motor-vehicle registration, an estimate was made of tributary motor vehicles by assuming that they would pass the station in proportion to their remoteness considering only the counties in tributary areas. In other words, of the total cars registered in the various counties, a certain percentage will contribute potentially to the daily traffic density at a fixed observation station. The writer has estimated this percentage as some ratio of the relative distances or remoteness from the observation station.

A typical analysis is shown in Table 10 for the station at Spring Hill, Tenn., near the Williamson-Maury County line. The percentages in Column (2) varied with the distance from Spring Hill and from a knowledge of the topography in the area.

The local travel at Spring Hill in 1926 was 573 vehicles per 12-hour day, which was a ratio of travel to weighted registration of 0.091. If two main thoroughfares are parallel across a county, certain vehicles will be tributary to one highway and others will flow over the other highway. About twenty stations were studied in a similar way, and it was found that the weighted motor-vehicle registration was ten times the local travel at the stations.

It is assumed, therefore, that the travel at other unobstructed stations will be approximately one-tenth the tributary motor-vehicle registration (see Table 11). An estimate was then made of the motor-vehicle registration tributary to all the proposed bridge sites. This was done by projecting the curve of registration from 1920, through 1927, to 1940. Many factors cause the registration to change, but all of them can hardly be estimated in advance. The trend of the preceding seven years was probably the best information at hand and, therefore, was used in the study. The population was estimated from the Census reports and the registration was taken from the records of the Department of Finance and Taxation through 1927.

TABLE 10.—ESTIMATED NUMBER OF REGISTERED VEHICLES THAT CONTRIBUTE TO TRAFFIC DENSITY AT SPRING HILL STATION.

County.	Percentage of total cars registered that contribute to traffic.	Cars registered in county.	Weighted values.
(1)	(2)	(3)	(4)
Williamson.....	80	2 908	2 326
Mauzy.....	60	3 164	1 898
Giles.....	30	2 655	797
Lawrence.....	30	2 315	695
Marshall.....	20	1 917	383
Hickman.....	10	1 115	112
Lewis.....	10	644	64
Total.....	....	.....	6 175

The weighted value taken is that obtained by assuming that the percentage of the cars tributary to the station varied with the distance from the source to the station. Some of the percentages are somewhat arbitrary and were determined from a personal knowledge of the topography and characteristics of the sites.

1	Huntingdon.....	7 000	610	0.087
Totals, or average.....		74 360	7 289	0.097

A typical analysis is given in Table 12 for Route 15 at the bridge over the Tennessee River between Waynesboro and Selmer, Tenn. (Bridge No. 3, Fig. 11).

Weighted registrations were obtained in a similar manner, using the actual registrations for each county each year (see Table 13).

The local unobstructed travel, therefore, is estimated at 340 vehicles in 1930, 385 in 1935, and 400 in 1940.

*Large Cities.*—The four large counties contain 48.5% of the motor vehicles registered in the State. It is desirable, therefore, to study the effect of motor-vehicle concentration in the large cities. Fortunately, information was available for this study. During the 1926 count, automobile license numbers were listed at more than forty stations. From the records in the Bureau of Registration, the location of ownership was determined and a tabulation was made for Davidson, Knox, Hamilton, and Shelby Counties, which include the Cities of Nashville, Knoxville, Chattanooga, and Memphis, respectively. Fig. 11 (a) shows by contour the number of cars per day originating in Davison County as they traveled throughout the State of Tennessee in 1926. The composite map (Fig. 11 (b)) shows the effect of nearly 50% of the automobiles of the State on the travel at the several bridge sites.

TABLE 12.—TYPICAL ANALYSIS OF POPULATION TRAFFIC AT THE BRIDGE AT SAVANNAH, HARDIN COUNTY, TENN.

County.	Percentage of total registration effective.	POPULATION.		ESTIMATED POPULATION THAT CONTRIBUTES TO TRAFFIC AT THE SAVANNAH BRIDGE.	
		1910.	1920.	1910.	1920.

Bridge No. 1 at Loudon, for example, is between Knoxville and Chattanooga, on the primary system (Fig. 11) and a large flow may be expected. Bridge No. 6, at Kyles Ford, is not on the primary system; it lies in a remote section of the State, and, consequently, serves very few vehicles from the large counties.

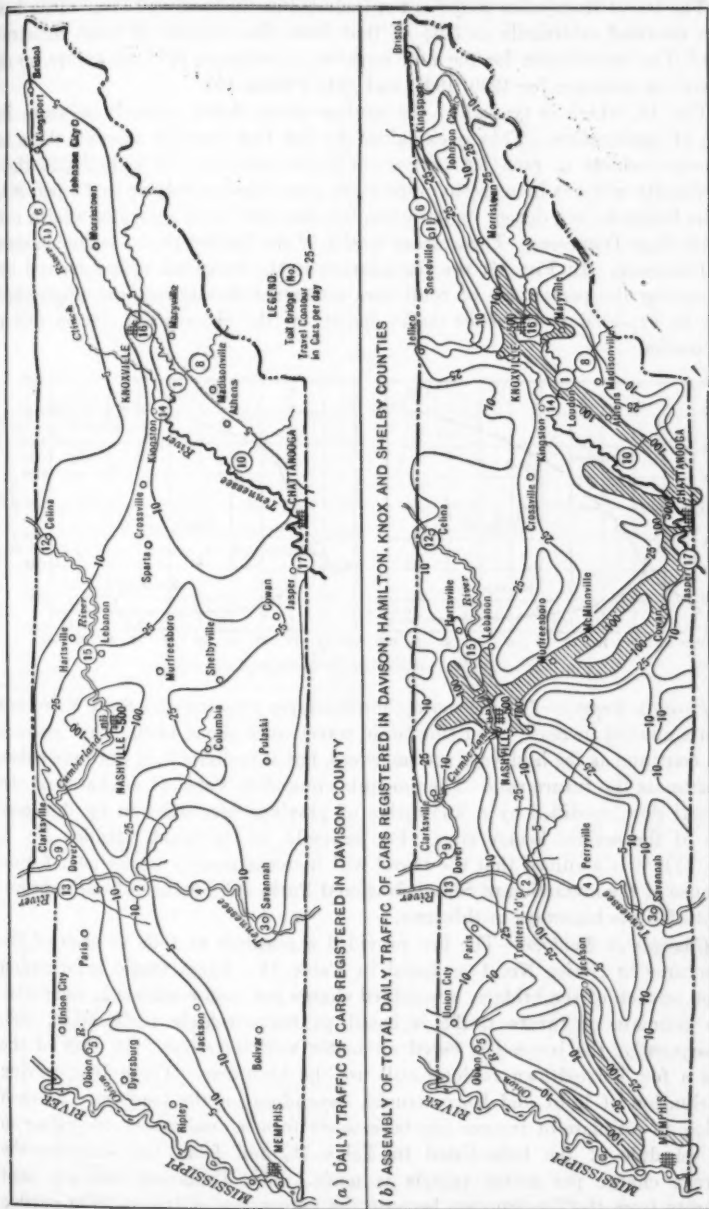

FIG. 11.—TRAFFIC MAP OF TENNESSEE FOR 1926.

The travel from other counties not included in the local and large cities has been assumed arbitrarily as 50% of that from the counties of large registration. The registration for the four counties is projected into the future, so as to give an estimate for 1930, 1935, and 1940 (Table 13).

Fig. 12, which is typical of the studies made, shows a steady decrease in rate of registration. This is explained by the fact that, at present, there is 1 motor vehicle to each 5.4 persons in these counties. It is probable that the density will not increase to much more than 1 motor vehicle to 4.5 persons. Some States have a denser registration, but they also have a greater wealth per capita than Tennessee. The average wealth of the United States is double that of Tennessee. In Fig. 12, the registration is the weighted value, derived by estimating the percentage of total cars registered throughout the State that may be expected to influence traffic density at the observation station under discussion.

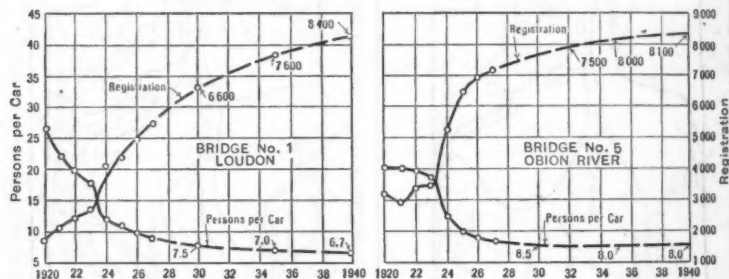

FIG. 12.—TYPICAL CURVES OF WEIGHTED REGISTRATION.

*Foreign Travel.*—On the main thoroughfares crossing the State there has been a marked increase in outside State travel since about 1926. This increase will continue as the highways are improved, but it is difficult, if not impossible, to estimate the future rate. The amounts entered in Table 14 are based on the present flow, modified by a knowledge of previous increase and by the location of the several bridge sites. For example, at Savannah (Bridge No. 3, Fig. 11), it is assumed that the travel will increase greatly in the near future because of the attraction of Shiloh National Park, and because of the improvement of State highways in this area.

*Charges at Bridges.*—The law provided a schedule of tolls at each of the structures in Series No. 1 as listed in Table 15. From traffic information taken at each of the bridges, a weighted charge per motor vehicle is computed. The estimate of future traffic is based on motor-vehicle registration, and, consequently, the income is based on motor vehicles alone. At each of the sites a few horse-drawn vehicles still use the highways. There is a varying distribution of light and heavy trucks, depending on the location. At each bridge an estimate of income has been made from actual travel, according to the schedule of the tolls listed in Table 15, and from this estimate the average charge per motor vehicle is made. The Tennessee cars are kept separate from the foreign cars because the percentage of trucks from outside

8	One-horse vehicle, with draft animal and driver.....	0.15	0.10
9	Two-horse vehicle and two draft animals and driver.....	0.25	0.15
10	Extra draft animals or horses or mules, each.....	0.05	0.05
11	Cattle, sheep, hogs, or other domestic animals, other than horses or mules on foot, each.....	0.02	0.02
12	Circus animals, other than those specifically mentioned in Items 8, 9, 10, and 11.....	0.25	0.25

the State is very small. The average charge for Tennessee motor vehicles is obtained by dividing the total receipts for the day by the total motor vehicles passing the station. The charge for foreign automobiles is obtained by adding to the amount received for the automobiles, one and one-half times 5 cents, making the charge for Bridges Nos. 2, 3, and 4, equal to 57.5 cents, and for Bridges Nos. 1, 5, 6, and 8, a charge of 32.5 cents. A sample computation is given for the Loudon Bridge (No. 1, Fig. 11), as follows:

Automobiles .....	640 $\times$ \$0.25 =	\$160.00
Passengers .....	1300 $\times$ 0.05 =	65.00
Light trucks .....	32 $\times$ 0.25 =	8.00
Heavy trucks .....	35 $\times$ 0.50 =	17.50
Trailers .....	1 $\times$ 0.25 =	0.25
Horse-drawn .....	1 $\times$ 0.15 =	0.15
Horse-drawn .....	5 $\times$ 0.10 =	0.50
<hr/>		<hr/>
640 + 32 + 35 = 707 vehicles =		\$251.40
707 $\times$ 35.5 + =		251.40
\$0.25 + 5 $\times$ \$0.015 =		\$0.325

The average number of passengers per car in Tennessee, as shown by previous counts, is 2.5 persons per car. Data taken at the ferries indicate a similar number of passengers. An automobile, therefore, will pay 25 cents for driver and car and 5 cents additional for each passenger.

To obtain the daily estimated tolls for 1930, 1935, and 1940, Tennessee travel is multiplied by the average charge for each station, and the foreign travel is multiplied by 32.5 cents, or 57.5 cents, according to the schedule of tolls fixed by law. The weighted charges for each bridge in Group 1 are listed in Table 16.

Foreign.....							

*Expectancy.*—In making an estimate of the travel at the several bridges, free flow was assumed from all the tributary area. This assumption is far from the truth for many of the bridges proposed. Some of the locations are in areas where highways will have to be constructed. The estimates made from the curves, therefore, are modified as nearly as may be to suit the station in question.

Traffic was counted in August, 1927, at all the stations. An estimate has been made of the probable local flow from the motor-vehicle registration. Table 17 gives the actual and estimated travel for 1927 and shows the percentage that the actual travel is of the theoretical. From Table 19 and a

knowledge of the particular locations and the progress of highway improvement it is possible to derive the percentage expectancy for the several sites.

TABLE 17.—PROBABLE LOCAL TRAFFIC FLOW OVER BRIDGES IN THE FIRST SERIES.

5	600	750	80
6	25	125	20
8	155	325	48

\* See Fig. 11.

*Expected Income.*—Having tabulated the probable travel for 1930, 1935, and 1940, it only remains to compute the income for each year modified by the expectancy as listed in Table 14. The specified toll charges are given in Table 15 and simple multiplication therefore produces the result shown in Table 18.

\* Estimated cost.

All the bridges of this group have been let to contract. The costs for each structure and the cost for the whole group, therefore, are approximately known. The probable annual cost may be easily estimated. Table 19 gives the estimated annual cost and the probable period required to retire the cost of construction.

W. W. CROSBY,\* M. Am. Soc. C. E. (by letter).—Concerted and noteworthy surveys to develop the relations between the use of roads and their design and upkeep were made prior to 1924. The Final Report of the Special Committee of the Society on Materials for Road Construction† shows that traffic was then recognized as “one of the most important” factors in the selection of the type of construction “considered from the standpoints of both economy and efficiency.” In Section 4 of The American Highway Engineers Handbook, the even wider effects of traffic are pointed out, and considerable detail as to traffic censuses is included.

In the discussion‡ of a paper by Mr. H. R. A. Mallock, on “Construction and Wear of Roads”, Mr. W. C. Copperthwaite has referred at some length to the wear as compared with traffic, citing London statistics of the latter, and many other contributors to the discussion recognized the relation of use to design and costs.

Reference to the *Proceedings* of the Association Internationale Permanente des Congrès de la Route will show that, since 1908 when this Association was organized, the relation of “use” to “costs” and other features of highway design and execution has been prominent in the minds of highway engineers and authorities all over the world.

Even Macadam and Telford were alert to the relation of “use” to “results” and, in his “Remarks on the Present System of Roadmaking” (1820), Macadam gave some suggestions as to the establishment of these relations.

Probably these scattered references to the extensive bibliography of traffic statistics will suffice to indicate the age of the consideration given to the subject.

† *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1388.‡ *Minutes of Proceedings*, Inst. C. E., Vol. CLXXVIII (1908-09), Pt. IV, p. 134.

The recent traffic surveys in Ohio are, of course, interesting, even if any novelties revealed by them are local, and confirm certain facts or principles indicated elsewhere. It is through what might be called the "integration" or "summation" of such local facts that a proper perspective for the scientific side can be obtained.

The great difficulty in the United States since the beginning of modern road work about 1895, has been that the use statistics concerning highways have always been behind, a kind of a "tail to the dog" of traffic development. Now, that more funds are available for the capture, examination, dissection, or analysis of this "tail", its importance is attracting attention from even others than highway engineers.

In some quarters there seems to be a tendency to make "the tail wag the dog"; that is, some argue that all features of a highway design should be based solely on actual or estimated traffic figures. The writer still argues that, of course, proper design demands consideration of traffic data, but he contends, "in and out of season", that after such consideration should come thought for perhaps more immaterial things. As the standards of living rise, pleasure and comfort make their demands for consideration, in addition to those of economy.

CHARLES RANDOLPH THOMAS, JR.,\* M. Am. Soc. C. E. (by letter).—The analysis made by Mr. Schlesinger shows rather clearly the importance of a study of population figures in planning roads. "The volume of highway traffic in an area is largely a function of the population of the area," as stated and proved by the author for Ohio, is also a fundamental proposition laid down by the late A. M. Wellington, M. Am. Soc. C. E., as applied to railroads. The development of modern highway traffic is producing conditions that are more and more like those that apply to railroads and telephone companies. Similar methods of analysis, which have reached a high degree of refinement in railroad and telephone traffic studies, may be applied with some degree of success to an analysis of highway conditions.

For purposes of predicting future traffic on a route, the great value of a traffic survey seems to be that it establishes the fact that highway traffic in general varies with population. In other respects, a traffic survey is like "locking the stable door after the horse is gone." The traffic is already there. Just how much traffic may be expected and what set of conditions will produce a given traffic is the information that the projector of a highway wants.

In cases where the traffic did not seem to vary so exactly with the population on the State roads, the author states that other roads carried the traffic. Might it not also be assumed from the same data that the economic location of the State road was poorly made—the road was not in the right place?

Another interesting conclusion is that only 14% of the traffic exceeded a 50-mile limit of trip—through traffic is relatively small. An analysis of traffic from the standpoint of the area served would seem to be possible, and such an analysis should give interesting and useful information, especially in predicting traffic.

\* Editor, *Good Roads*, Chicago, Ill.

The determination of the potential traffic in the area would give maximum figures useful in designing. The variable of "attraction of traffic" is eliminated by assuming that the road properly improved will get all the traffic, much of which is now going by other routes. This, of course, applies only to the local 50-mile haul traffic, which in Ohio is 86% of the total.

The subject is one that might be discussed and elaborated at length with interesting results. Suffice it to say that the old railroad principle of location holds true, namely, that there is one best route between two points or a group of points; that this route should be found and improvement made in proportion to traffic to be anticipated when the traffic area is developed to its full present possibilities; and if funds are available it may be wise to anticipate future traffic possibilities of the area.

The economic study of highways as discussed by Mr. Schlesinger also involves: (1) The political and social aspects and the effect of taxation and intangible benefits; (2) the more easily measured costs of construction and maintenance and the adjustment of such costs to individual vehicle operating costs; and (3) the monetary savings or profits, if any, from improved transportation facilities.

By limiting the subject to highways constructed by private enterprise under reasonable charters from the State, many social and political aspects are eliminated. This permits a study of the subject from the standpoint of commercial success or failure as measured by the yardstick of business—money profit or loss.

It is the purpose of this discussion to review briefly the development of old and modern toll roads and to present a method of studying certain of the economic factors to be considered by the engineer in making a survey of a proposed toll-road project under modern conditions, so that he may determine within reasonable limits of error the relative profit or loss of the project.

*Toll Roads in the United States and England.*—Immediately after the American Revolutionary War there was an insistent demand for improved roads, but the States and counties were too poor and the people would not tolerate excessive taxes for road building. Therefore, the English method of financing and building roads was adopted. The various States granted to private companies the right to build roads and charge tolls for their use.

The fundamental principle of this turnpike system was to transfer the cost of road building from the State to the users of the road. In the beginning only the main roads were to be turnpikes. The weakness of the turnpike system was that there grew up an endless number of isolated companies frequently under-financed and operating in a territory in which the volume of traffic would not permit an adequate return on the investment, even with tolls amounting to all that the traffic would bear. (A similar situation existed later with respect to some railroads). These private turnpikes were so short that the traveler was annoyed continually by the obstruction of gates as he passed from the road of one company to that of another.

Conditions in England under this form of turnpike system have been described by Mr. Edwin A. Pratt.\* He states that when the need arose for

\* "History of Inland Transportation and Communication in England," by Edwin A. Pratt, p. 82.

better roads in any district, a group of land owners and others would apply to Parliament for authority to raise a loan to be used for improvements. They would then build or repair a road and set up gates or bars at which they could exact tolls for the payment of debts and for maintenance charges. In theory, this was intended as a temporary arrangement and that after the first cost was paid the road would become free for public use. Charters were granted for limited periods of about twenty years and these were renewable if the debt remained unpaid at the end of the period. Mr. Pratt states that:

"\* \* \* one result of the excessive localization of the turnpike system was that trusts of absurdly large proportions were created to look after absurdly small stretches of road."

The turnpike system, accordingly both in England and America, fell into disrepute; it was killed by mismanagement and lack of business due to railroad competition before the coming of the revolution in highway transportation which was brought about by the motor vehicle. At present (1929) there are only a few of the old-fashioned turnpike companies in existence.

Nevertheless, the era of road building, brought on by the introduction of private initiative, marked the beginning of a period of rapid expansion in general business due to improved transportation facilities both in America and England. This was the era of the great engineers, Macadam and Telford.

Under modern conditions, with highway traffic completely motorized, only a few roads have been built by private capital. The failures of the Nineteenth Century are still too fresh in the minds of the people, and there is a widespread prejudice against toll roads, in many cases without sound reasons.

*Toll Roads in Italy.*—The outstanding modern development in toll highways built to care for motor traffic is the "autostrade" system in Italy. It has been projected and partly developed under the engineering leadership of Picero Puricelli. His basic ideas on projecting these motor roads, as expressed in a communication to the writer, are as follows:\*

1.—Motorways should supplement the ordinary highways rather than compete with them, and for this purpose should be designed for the greatest degree of efficiency consistent with the expected traffic.

2.—These roads have a special function and should be constructed only where peculiar local conditions of traffic, etc., indicate their advisability.

3.—Toll financing of motorways is not a characteristic necessity, but it is a legitimate means of obtaining income from a capital expenditure.

4.—In their projection, construction, and operation, motorways are comparable to railroads. They should be designed for express traffic in a class distinct from local highways.

5.—Under private enterprise, the selection of routes and the execution of a project are regulated by the presence or absence of factors that insure a satisfactory financial return. Political pressure is reduced. Motorways should be built only where traffic studies give promise of a sufficient income.

\* Also, see, "Motor Roads and the Milan Lakes," by Picero Puricelli, *Autostrade*, Milan.

6.—Existing roads need not necessarily be abandoned. If they are improved they may serve as feeders to the express highways.

7.—The mere presence of poor roads that are the result of improper maintenance does not justify the construction of a motorway.

8.—Existing roads often do not meet the needs of motorways because they are narrow and winding, they have bad surfaces, sharp turns, concealed intersections, interurban traction lines along the side, grade crossings, and inadequate traffic control. They are inclined to pass frequently through congested areas, and they are subject to the nuisances created by dust. These conditions are most easily controlled by designing separate express motorways. It is estimated that the Italian Government will take over the present motorway system before 1980.

*The Motorway from Milan to the Italian Lakes Region.*—This 60-mile highway was begun in 1923 and placed in operation in 1925. It is controlled by a limited liability company and cost approximately \$75 000 per mile. The obligations were issued by the company and the Government guarantees the payment of interest, in return for which it takes over the control of the road in 1973.

In 1926, the receipts and expenditures were as follows:

Receipts:

Trip tickets .....	\$185 000
Season tickets .....	30 000
Advertising space .....	25 000
Total receipts .....	\$240 000

Expenditures:

Operation and maintenance.....	\$ 80 000
Sinking fund and loans.....	72 500
Amortization of capital.....	12 500
Interest charges .....	70 000

Total expenditures ..... \$235 000

The balance sheet thus showed a net profit of \$5 000. There was an average of 700 vehicles per day of all kinds using the motorway during 1926 and in 1927 the daily average was 900. During the first months of 1928 the average was greatly increased.

*Tolls.*—The toll schedule in Table 20 was in effect for two years, after which a 20% reduction was adopted. Subscription cars are good for one year over the entire system, and provision is made for companies owning several vehicles; that is, a 20% reduction for two vehicles, 25% for three, and 30% for four or more. Public service motor vehicles are not issued subscription cards and are charged triple tolls. Vehicles with solid rubber tires pay double toll.

*Entrepreneur Studies.*—The inception of a toll-road project presents certain speculative questions as to the profits possible from the investment of capital. These may be listed somewhat as follows:

1.—Will the financing, construction, maintenance, and operation costs permit income with a sufficient margin to provide for dividends and the retirement of the capital invested?

2.—What are the sources of present and future traffic and how productive of income traffic will be these sources?

3.—What are the details of immediate and future construction and operating expense on the most economical route and just where should this route be located?

4.—What is the proper investment to make so that traffic will be handled most economically and, at the same time, produce the greatest net revenue?

5.—What kind of franchise may be obtained from the State or local authorities and what are the conditions of the franchise, such as duration, recapture, renewal, etc., that must be met?

6.—What measures will be necessary to attract traffic to the highway and what will be the cost of a measure such as advertising?

TABLE 20.—TOLLS PAID ON MILAN-LAKES MOTORWAY.

To answer some of the questions is the mission of the engineer employed to make a preliminary report; the answer to others has an element of speculation which will be discovered only when the highway has been in operation over a period of years.

*Scope of Preliminary Engineering Report.*—The scope of the preliminary engineering report suggested is limited by the questions asked by the entrepreneurs as to the feasibility of the project, and by the time and funds available for the investigation.

Two basic ideas must be kept in mind in making such a report: First, that a motor vehicle has freedom of movement and will find the economic route that offers convenience, speed, and economy; and, second, that the best location between maximum traffic sources must be found and there must be placed on that location the type of road (pavement, signaling, crossing, etc.) demanded by traffic, with due regard to future traffic at the end of a term of years.

The report might well include: (a) A traffic reconnaissance of the area through which several possible ground locations might be made; (b) estimated traffic from various sources on the approximate paper location made from a study of the area, consideration being given to possible alternate routes at certain points; (c) an estimate of revenues both present and possible in the future, as indicated by the population and industrial studies made of the area tributary to the route; (d) estimates of construction and maintenance costs; (e) estimates of operating costs; and (f) summary of financial and charter requirements.

Conclusions and recommendations as to the feasibility of the project might well be summarized at the beginning of the report.

*Traffic Studies of the Area.*—The study of traffic within the area tributary to several possible locations in the general direction thought feasible for the projected highway is limited. Mr. Schlesinger has found that, over large areas such as a State or parts of a State, the traffic on the roads varies directly as the population. The accumulation of traffic on a railroad route was found by Wellington\* to vary as the square of the number of traffic sources, and it is believed that for limited areas the traffic may develop in even a larger ratio on highways.

The author states that the ratio of through traffic (trips of more than 50 miles) was approximately 30% in Ohio; that bus traffic was 1.5% of the total passenger traffic; and that trucks were 9.5% of the total traffic on the State system.

In a study of comparative rail and highway tonnage made in Ohio in 1925† the proportion of motor-truck tonnage decreased with the length of haul, as shown in Table 21. However, with the improvement in motor vehicles and methods of operation the length of profitable haul is gradually increasing.

The factors entering into a determination of the traffic in the area have been summarized elsewhere by the author as follows:‡

"The formulation of a method for approximating the traffic on a given highway without the necessity of a field survey is within the range of possibility, using the data available as a result of transport surveys. It is believed that the problem is capable of solution if proper consideration is given to such factors as:

- 1.—The tributary area.
- 2.—Population density.
- 3.—Motor vehicular registration.
- 4.—Character of population—urban or rural.
- 5.—Classification of predominating industry—industrial or agricultural."

Maximum traffic will, of course, be the sum of the potential traffic of the area and the foreign traffic coming into the area. However, it is scarcely possible that this maximum can ever be attained.

\* "The Economical Theory of Railroad Location," p. 713.

† Traffic Survey by U. S. Bureau of Public Roads and Ohio Highway Department, reported in *Roads and Streets*, October, 1927, p. 427.

‡ Extract from an address before the American Association of State Highway Officials, 1926.

*Traffic Reconnaissance of the Projected Line.*—Traffic studies of the projected location of a route may be conducted in sections covering a width approximately equal to the normal maximum trip of a motor vehicle.

The comparative weight to allow in securing local traffic for the road; the sacrifices of distance necessary in order to reach certain traffic sources that accumulate traffic; how near to run to cities and towns; the distance gains made in by-passes; and the intermediate changes in alignment to shorten the route, are all matters that must be considered as affecting the total volume of traffic. While the traffic on the road is increased by lengthening the line, if that lengthening is too great drivers become discouraged, the road possibly becomes too congested for the service rendered, and traffic will seek new routes. The effect of a secondary road on the traffic on the main road also must be considered.

TABLE 21.—PROPORTION OF MOTOR TRUCK AND RAILROAD NET TONNAGE  
ACCORDING TO LENGTH OF HAUL FOR AVERAGE MONTH, 1925.\*

Length of haul, in highway miles.	MOTOR TRUCK.		RAIL (CARLOAD).		RAIL (LESS THAN CARLOAD).		TOTAL.	
	Tons.	Percent- age of total truck and railroad tonnage.	Tons.	Percent- age of total truck and railroad tonnage.	Tons.	Percent- age of total truck and railroad tonnage.	Tons.	Percent- age of total truck and railroad tonnage.
Less than 20	6 091	84.5	1 112	15.4	10	0.1	7 213	100.0
20 to 30	5 973	54.7	4 303	44.0	145	1.3	10 921	100.0

100 and more	157	2.3	5 290	77.4	1 353	20.3	6 820	100.0

\* Based on tonnage between Columbus, Ohio, and thirty cities having rail connections, report of U. S. Bureau of Public Roads.

It should be remembered that no single road is completely independent of other competing roads, and when congestion comes there is a tendency for the traffic to "spill over" to competing routes. However, traffic has a tendency to concentrate on certain routes that afford convenience, speed, and economy.

*Factors That Affect Traffic.*—The function of a highway is to provide a smooth, convenient route from the point of freight or passenger departure to the destination, and it must not be assumed that traffic will come to a road just because it happens to be a good road. Other factors enter the problem.

Certain roads acquire a name for being good roads and get the traffic apparently for no better reason than the Biblical allusion, "to him that hath shall be given". Likewise, the saying, "give a dog a bad name and it will stay with him", applies as well to highways and possibly explains why some roads lose traffic.

An apparently inconsequential matter that causes a road to miss a town may result in a loss of traffic that is out of all proportion to the advantage gained. The loss of traffic due to missing a town at a distance great enough

to make access to the road difficult must be balanced by the traffic gained by the other, perhaps shorter, route.

Wellington states that "errors in the original laying out of a route, unlike errors in subsequent management, are mainly irremediable—a kind of fixed charge for folly forever". He also estimates that the loss of traffic\* varies from 10 to 25% of the total traffic to be obtained by going directly through the center of the town for each mile a railroad passes at a distance from the center of the town. These figures, of course, apply only to railroads, but they give a guide as to a method of computing the effect of moving a highway away from a town.

The factors that cause variations in the location of a route are: Manufacturing towns that originate a large amount of traffic; special industries that must be served; the existence of competing routes; and special reasons that arise, and are peculiar to the existing conditions. An attempt to pass through the center of gravity of the population of two towns by going between them often leads to fallacious results unless more than two towns are considered.

Methods for reconnaissance surveys have not appeared in print so far as the writer has been able to determine. The method outlined herein is suggested as a procedure to be followed only as conditions justify.

The first step in a traffic reconnaissance survey is the collection of all available data in the form of published U. S. Geological Survey maps to be used in making notes of data and all reports as to motor-vehicle registration in the countries to be traversed. Reports showing the location of industrial plants, tonnage of farm crops marked at various cities, census figures as to population of counties, and similar material, also will be useful. The various civic chambers of commerce can furnish valuable information.

Since it may be roughly estimated that about 85% of the motor-vehicle travel will not go more than 50 miles on a single trip, and about 70% will not go more than 30 miles, it may safely be assumed in general that a margin of 50 miles, 25 miles on either side of the proposed line, will be sufficient to embrace the traffic that will be attracted to the road.

The next step is to make a careful study of the 50-mile strip of territory, estimating the tonnage to be hauled. This tonnage can easily be converted into the approximate number of motor-vehicle trips necessary to transport. To estimate pleasure car traffic the registration in the area may be multiplied by about 5 000 miles of annual use per year for each car, and this, in turn, may be changed to trips past a certain point with a suitable correction. Through traffic may be estimated from traffic counts at selected points, suitable corrections being made for seasonal variations and week-end concentrations.

The third step is to post men at selected points, determined by a study of maps and personal examination of the roads, and to inquire about traffic and such matters as the possible sale of filling stations or revenue from other similar sources. The men should count the traffic on selected days of the week covering 24 hours each day.

\* "The Economical Theory of Railroad Location," p. 63.

From the traffic counts and the other data available, a rough approximation as to existing traffic can be obtained. This estimate can be corrected for attraction of traffic to the new road and the influence of competing roads. To determine future traffic, the potential traffic in the area based on tonnage hauled and registration predicted, as well as population increase, can be estimated as the maximum regional traffic. The determination of increase in through traffic is not so simple, but may be estimated from increased registration in the State, by considering that through traffic, in normal cases, is not more than 25% of the total traffic.

Future traffic may be estimated from the slope of the curves of traffic by years, especially the curve of motor-vehicle registration in this area. Predictions more than five years in advance are likely to be very misleading.

*Evaluating Distance and Time.*—The saving of shortened distance to transportation agencies is readily determined by a simple computation using the method of W. H. Connell, M. Am. Soc. C. E.\* For example, with an operating cost of about 10 cents per mile and a traffic consisting of 85% light motor vehicles and 15% trucks, the cost for each 1 000 ft. over a paved road, or all-weather road, is about 2 cents for each vehicle. For 1 000 vehicles per day the cost would be about \$20, or \$7 300 per year. The saving per mile per year due to shortening the route is, therefore, approximately \$38 700, or \$774 000 over a period of 20 years, the life of many bond issues.

The value of a car-minute as determined for congested areas adjacent to New York City by the State of New Jersey in studies of highways was: For trucks, 2.3 cents; for buses, 2.1 cents; and for pleasure cars, 1.0 cents. In applying these figures to single grade crossings† it was found that on a highway carrying four lines of traffic averaging 20 000 000 vehicles per year there was a loss of 7 000 000 car-minutes, or \$154 000 per year which, capitalized at 4%, equals \$3 850 000, the sum that might reasonably be invested to eliminate this delay.

*Location, Curves, and Grades.*—The effect of location, curves, and grades on the first cost is direct and must be considered from the standpoint of the initial investment in the road—whether it is desired to build a cheap or expensive line.

Having determined from the consideration of the various traffic surveys, the traffic-source points through which the projected line must pass, the problem becomes one of finding the straightest and most economical line through these points. This line is located on the ground by field surveys of as many routes as seem feasible, using the methods familiar to highway engineers.

The elimination of grade crossings with railroads and intersecting highways is one of the largest items of expense and must be considered carefully because of the liability of a private corporation to damages for accidents occurring on its property. By observing care in locating the intersections of highways so that they meet at different levels the cost of grade separation

\* Report of Investigations of Paving and General Highway Conditions by the Commission Appointed by the National Paving Brick Manufacturers Association, p. 19.

† "Economic Theory of Highway Location," by F. Lavis, M. Am. Soc. C. E., *Roads and Streets*, October, 1927, p. 443.

can be reduced. On level ground a treatment of the type shown in the sketch, Fig. 13, may be adopted. It is desirable to have as few intersecting highways as possible for safety considerations, but it is also desirable to have as many traffic sources as possible from the standpoint of local revenue. The private drive nuisance on public roads, which permits the entry of vehicles on the road at practically any point, is eliminated when the road is on a protected right of way with sharply defined places of entry and departure for traffic.

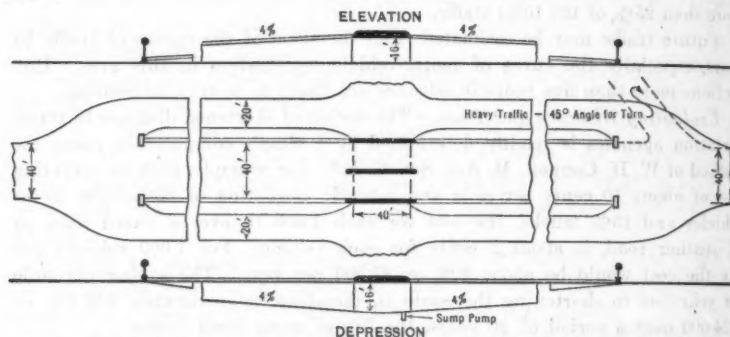

FIG. 13.—PLAN FOR HIGHWAY GRADE SEPARATION ON LEVEL GROUND BY EITHER ELEVATION OR DEPRESSION OF ONE ROADWAY.

The saving in time by the elimination of delays at crossings and other points of congestion will be an important factor in making the road more attractive to traffic, thereby increasing revenue. The capacity of the road is also increased by the time saving.

Signaling for traffic control while entering or leaving the road and en route should be reduced to a maximum necessary for safety, in order to avoid delays and annoyance for the traveler. The amount expended on signaling will vary with the number of danger points on the road.

*Estimating Revenue.*—Revenue to a toll road may ordinarily accrue from (1) use charges or tolls for various types of vehicles; (2) advertising space and concessions leased; and (3) rent of surplus land usually obtained in acquiring right of way.

Toll charges for various types of vehicles should be applied as simply as possible. In Italy, various categories based on the horse-power of the vehicles are in use; term or season tickets are issued, in addition to ordinary trip tickets.

The value of connecting routes as sources of both local and through traffic is self-evident. These routes also intersect other roads, in most cases, and one of the problems of the toll highway officials is to influence this traffic to use the toll roads because of the superior advantages offered. There also exists a competition with other roads that parallel the toll highway and here, again, a problem is evident.

From these and other factors it is apparent that the chief problem from the standpoint of revenue is the sale of transportation facilities which may

have sufficient advantages over other available facilities so that the traffic is willing to pay a premium to enjoy these advantages.

The sale of transportation, like the sale of anything else, is based on making the user of the facility want it, and the same effort and technique must be employed as in the sale of any other commodity. In this sales effort, advertising plays an important part. Advertising campaigns based on the recommended procedure of specialists in such work are advisable and undoubtedly will have an important effect in increasing the travel on the road.

Some revenue will be derived from the leasing of billboard space on the right of way, but it has the disadvantage of obstructing the view of the landscape and makes the highway less attractive to the traveler. Concessions such as gasoline filling stations, telephones, refreshment stands, etc., are also a sure source of revenue.

The leasing of excess land owned by the company may be a source of revenue which, in some cases, may be used to offset the carrying charges of such land. It is inevitable that in acquiring right of way, whether by easement or purchase, there will be much of it not used for highway purposes. With the construction of the road this land will increase in value in most cases and may be sold later at a profit.

The ratio of local traffic (not more than 50-mile trip) as determined by traffic surveys in several parts of the United States, is from 10 to 25% of through traffic varying with the season, the section of the road, and the section of the country. It is quite evident, therefore, that the bulk of the revenue traffic will be local in nature and, at present, will be for the most part light pleasure automobiles. It is highly probable, however, that a decided increase in truck traffic will be seen within the next decade.

*Construction Costs.*—These costs, of course, depend much on the investment in roadway and protective works which the study of present and future traffic indicates will be profitable for the location selected. In determining the first cost of a pavement, the relative proportion of that cost necessary for maintenance must be considered as well as that of renewals at the end of its useful life.

*Financial Study of a Toll Road.*—For purposes of outlining a method of studying the working of a proposed toll-road project, consider a hypothetical case.

A toll highway is proposed to connect two cities of about 1 000 000 population each, that are about 80 miles apart. Between these cities are ten smaller cities varying in population from 5 000 to 50 000 which will be by-passed but tapped with short branch roads. There are ten entry points to the highway at the small cities and also ten other minor intersection points of industrial centers at which entry may also be made, making a total of twenty-two entry points, including the two terminals. Initial traffic is approximated at 4 000 miscellaneous vehicles per 24-hour day.

The investment in the project is estimated roughly, as follows:

80 miles of operating highway at \$100 000.....	\$8 000 000
Working capital stock issued as needed.....	2 000 000
Total .....	\$10 000 000

The items that may be considered in the construction costs and the percentage of the total for each item for a road constructed at a cost of \$100 000 per mile may be approximated, as follows:

	Estimated cost.	Percentage of total costs.
Right of way.....	\$12 000.....	12
Grading and draining.....	15 000.....	15
Bridges.....	15 000.....	15
Crossing eliminations.....	25 000.....	25
Pavement.....	25 000.....	25
Miscellaneous protective works.....	5 000.....	5
Signaling and lights.....	2 000.....	2
Buildings.....	1 000.....	1
Total .....	\$100 000.....	100

A statement of the annual income and expense of the report might be approximately, as follows:

*Income.—*

Through traffic tolls, 1 000 vehicles per day at \$1.00.....	\$ 365 000
Local traffic tolls, 3 000 vehicles per day at 50 cents.....	550 000

G. F. SCHLESINGER,\* M. A. M. Soc. C. E. (by letter).—The discussion of this paper has been of an informative and supplemental nature, as the subject-matter was not such as to call forth comment of a controversial character. Highway engineers and authorities are agreed that the information supplied by a comprehensive transport survey is essential to the proper planning of a program for future improvements.

Mr. Simpson calls attention to the impracticability of securing as complete information in a city traffic survey as in the Ohio survey of rural highways, and questions the necessity of what might be termed non-essential data in solving problems arising from city traffic. As stated by the writer some of the information made available by the Ohio Transport Survey "might be classified as being outside the scope of practicality". However the data were obtained at very little additional expense and, without discussing their practical utility, it may be stated that they have been a valuable contribution to the general knowledge of the fundamental principles of highway traffic. It has occurred to the writer that a knowledge of the origin and destination of traffic would be very desirable in a city where conditions require the designation of a system of "one-way" streets.

It is somewhat surprising that, according to the Columbus survey, the proportion of traffic in the main city streets should agree so closely with that on the main Ohio rural highways (the State System). It would seem logical that the proportion on the main city streets, as compared to rural routes, would be less, due to the following causes:

- (1) The greater availability of alternate secondary city streets;
- (2) The better condition of the pavements on alternate secondary streets; and,
- (3) The tendency of city traffic to avoid congested and traffic control (manual and automatic) conditions on the main thoroughfares.

\* Chf. Engr. and Managing Director, National Paving Brick Mfrs. Assoc., Washington, D. C.

It would follow that there must be other counteracting factors in the case of rural main highway traffic. There is probably a greater percentage of pleasure traffic outside the city, that does not follow the most direct routes. The fact that the maximum daily traffic occurs on Sunday in the country and that it is a minimum on that day in the city, according to Mr. Simpson, shows clearly the use many city motorists make of their cars over the week-end.

In his discussion, Mr. Van Duzer mentions the importance of careful methods in forecasting future trends and also the securing of additional data that later might modify the general plan based on the original survey. There should be periodic "follow-up" surveys, which can be conducted on a much smaller scale. He also suggests the possible utilization of highway transport surveys in connection with the safe operation and control of traffic, with which, he states, future highway administration may be expected to concern itself. The operation of the State highways has been placed, to a considerable extent, in the hands of the State highway engineering executives, and properly so. Such duties as the erection of route markers and warning signs belong to them, and, in some cases, the highway police force is under their control. However, in the cities, the control of traffic is usually under the public safety, police, traffic, or other department without engineering administration and, in most cases, without engineering advice.

Mr. Thomas draws an analogy between highway and railroad traffic. There is, however, a decided difference in respect to the composition of passenger traffic in the two types of transportation. The Ohio survey shows that 44.6% of the passenger-car traffic on the State Highway System measured in passenger-car miles is non-business or pleasure traffic, while railroad traffic is more predominantly of the business variety. Railroad passenger traffic, also, is not carried in small mobile units subject in routing to the almost instant direction of a relative large number of individual operators. For this reason it would not be accurate to assume that a "road properly improved will get all the traffic, much of which is now going by other routes".

Mr. Thomas quotes from the original paper to the effect that 14% of the traffic exceeded a 50-mile limit of trip. This figure applies to truck traffic and approximately 30% of all traffic exceeded 50 miles per trip. However, Mr. Thomas is correct in his conclusion that highway traffic is primarily a function of local transportation and of the population of local areas tributary to the highway. The writer agrees that the formulation of a method for approximating the traffic on a given or projected highway route without the necessity of a field survey is within the range of possibility, using the data and principles established as a result of transport surveys already made.

Some of the principles established by the traffic studies in Ohio, and by other comprehensive surveys, have been applied by Mr. Thomas to the problem of determining the probable commercial success of a proposed toll-road project. His analysis, suggested method of procedure, and application to a hypothetical case are admirable. Nor can the writer offer any valid objections to

such private ventures in the transportation field, if they appeal to capital as profitable enterprises, assuming that the public interest receives the usual legal protection incident to quasi-public utilities. However, there is such decided opposition to toll roads in the United States that there is little probability of such enterprises being legally authorized until there is a great change in public sentiment. In the writer's opinion no legislative body, at the present time, could be persuaded to grant a toll-road company the right of eminent domain to condemn private property for the right of way required for such a project. While the gasoline tax is essentially a form of tolls, it has been termed a "painless tax" because of its method of collection. The motorist is not confronted with a barrier that will be closed to him until he has purchased a ticket. A projected toll road, as Mr. Thomas observes, would offer an excellent opportunity for the application of the principles of highway traffic flow in a purely economic study with social and political considerations eliminated. It is believed that in the future development of highway transportation in this country, as in the past, highway engineers will be required to deal with such social and political problems along with those of a technical nature.

That methods of approximating traffic are not only possible, but actually have been applied, is revealed in Professor Dougherty's description of the surveys in connection with proposed toll-bridge projects in Tennessee. The statement that "a 12-hour count taken in August, therefore, approximates the average 24-hour flow throughout the year", may give readers the impression—as it did the writer at first reading—that one 12-hour count during that month is all that is required for this approximation. The reference is to the average of daily 12-hour daylight counts taken during the month of August. The details of the analysis of probable traffic and consequent tolls are very logical and should be useful to those confronted with similar problems. The writer will inject the observation that the prevailing method of financing highway improvements by means of a tax on gasoline is essentially one of tolls.

Colonel Crosby calls attention to the fact that for a century or more highway engineers have recognized the utility of traffic data as factors in the design of roads and the selection of types of pavements. The writer believes that a more important and valuable utilization is in the establishment of a State-wide or regional plan for a future program of highway development. He agrees with Colonel Crosby that there is a benefit to society in the improving of highways that is indefinable and incapable of measurement in terms of traffic accommodation, or any other material units.

Paper No. 1737

### THE ENGINEER'S PART IN MAKING THE HIGHWAY SAFE\*

By A. H. HINKLE,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. E. W. JAMES, LOUIS P. BLUM, C. N. HAGGART,  
H. J. KIRK, W. W. CROSBY, VICTOR A. ENDERSBY, AND G. C. DILLMAN.

It is difficult to draw an exact line as to where the engineer's responsibility ceases with reference to safety on highways. Because the field is rather broad what is said here should not be questioned with reference to the exact limit of responsibility between any two classes of individuals.

Study shows that there are many contributory causes of accidents on highways, although any one accident may have its major source. For example, on a rainy day with the windshield blurred, a driver may have approached, at high speed, a sharp curve having no superelevation, where there were leaves on the wet surface, resulting in his machine skidding off the pavement. It is seen that six different factors may have contributed to the accident. Too frequently the driver of a machine that has been in an accident does not himself realize all the factors. This, in itself, may handicap him in profiting by his past experiences.

For discussion, the causes of accidents may be classified as follows: (1) Incidental to the operator himself, such as bad vision, sleepiness, dull sense, over-work, excessive speed, general disregard for traffic rules, etc.; (2) defects in the automobile, such as imperfect brakes, obscured vision due to poor curtains or large corner posts, glaring or too weak headlights, broken connecting rod, etc.; (3) highway conditions, such as sharp curves, steep grades, slippery surfaces, high crowns, narrow pavements or shoulders, steep ditch slopes, narrow bridges, holes in the surface, lack of superelevation, railroad grade crossing, etc.

\* Presented at the meeting of the Highway Division, Columbus, Ohio, October 13, 1927.

† Chf. Engr., Maintenance, Indiana State Highway Comm., Indianapolis, Ind.

The third class of accidents is primarily a problem for the highway engineer. About 30% of all the accidents recorded in Indiana in 1926 were due to highway conditions. It would seem that in a measure such statistics would show the degree of responsibility to be taken by the engineer. While limited finances and other restrictions must of course assume their share of responsibility for the engineer's acts, yet he must offer the proper advice to those to whom he reports. Hence, the engineer is primarily responsible for the proper design and upkeep of the highway so as to reduce to a minimum the conditions that contribute to accidents.

### CURVES

*Vision.*—A minimum clear sight of 500 ft. between any two points 5 ft. above the road surface seems to have been generally adopted for both horizontal and vertical curves. While this might be recognized as a desirable standard, it should ever be kept in mind that different conditions will affect the safety features connected with the sight distance, so that a clear sight of 400 ft. in one location may be no more dangerous than one of 600 ft. in another. For example, if the point in question is at the end of a long tangent in open country, where a high speed is normally invited, a short sight distance becomes far more dangerous than it would if it were closely bounded on either side by curves of lower degree which would normally slow down the speed of a vehicle. Also, in built-up districts where the speed is normally much lower than in open country, a shorter sight distance is permissible.

*Horizontal Curves.*—In open country where a high speed may be expected, it is desirable from a safety point of view, to limit curves to 5 or 6 degrees. Due to the continually higher speeds at which vehicles travel, it is best where the cost is not great to keep the sharpness of the curve several degrees lower than that considered dangerous at present, thus avoiding what may be a demand in later years to reconstruct on a flatter curve. In mountainous country, and in other strategic locations, it is necessary from an economic point of view to construct much sharper curves; but this may be done in such a way that the danger is not necessarily great. Due to the natural tendency of drivers to reduce speed on a curve, a 20° curve in one location may be no more dangerous than a 6° curve in another. The driver is bound to be more cautious in hilly country, full of curves and grades, than at the end of a long tangent with an unexpected curve.

Perhaps the better way would be to limit the curve to not more than, say, 6° sharper than any preceding curve ending within 200 ft. of it. From a safety point of view, small curvature, or small changes between adjacent curves, regardless of degree, may not necessarily be dangerous. In fact, due to the greater caution naturally taken by drivers on a curved line, it is possible that with the proper design an irregular line with low degree curves or a low differential may be safer than the average tangent. Statistics of accidents seem to show this to be true. Danger is a factor of speed, other things being equal, and, therefore, anything that contributes to a lower speed may result in fewer accidents.

Precaution should be taken to guard against using the maximum degree of curve where it is not necessary. In many cases where there is a  $10^\circ$  curve, a  $5^\circ$  curve could have been used just as well and even more economically because of the saving in pavement.

*Superelevation.*—Curves of  $2^\circ$  or more should be superelevated. This generally may be computed from the formula:

$$e = \frac{V^2}{15 R}$$

in which,

$e$  = the superelevation, in feet per foot of width;

$V$  = the velocity, in miles per hour; and

$R$  = the radius of curve, in feet.

In this formula, the speed is assumed at 30 miles per hour, with the maximum superelevation as 0.1 ft. per ft. of width.

The slight difficulty due to a vehicle slipping toward the inside of a curve on an icy surface, may be overcome by building a comparatively wide inner shoulder at such places at the normal shoulder slope. The outside shoulder for its full width should take the same superelevation slope as the pavement. On superelevated curves the crown of the road should be reduced to zero at the point of maximum superelevation.

*Widening on Curves.*—It is well to widen the pavement on all curves of  $5^\circ$  or sharper. The widening should be on the inside and the width, in feet, should be about 0.3 times the sharpness of the curve, in degrees.

Due to the added cost, the widening on concrete pavements is frequently omitted on a curve of less than 8 or 10 degrees. This may be justified on light traveled roads. In such cases it is necessary to give more care to the inside shoulder by maintaining an added width of stone or gravel that will prevent a rut from forming along the pavement. As an alternate to widening the curve, a spiraled curve is sometimes used. The spiraling is not a proper substitute, however, for widening on high degree curves.

Widening the intersection of important roads has a great value in reducing accidents, perhaps as much in impressing the driver more emphatically with the fact that he is approaching an important and hence dangerous intersection as in increasing the sight distance or giving more room for dodging the other vehicle. At a certain right-angled intersection, one of the two heavily traveled highways is in a cut for about 100 ft. back. This intersection was widened at all four corners to a 100-ft. radius. Although accidents had been numerous previously, not one has been recorded in the two years since the highway was improved. It is interesting to note how drivers slow down as they observe the widened intersection. Unconsciously, the improvement seems to impress the mind of the driver that there is danger ahead.

#### GRADES

From a safety point of view it is desirable to keep long grades down to 3 or 4%, if no material additional cost is entailed. On main heavily traveled highways it is extremely desirable to limit all long grades to 5% even at considerable expense. On secondary roads, 7% may be taken as a desired

maximum for long grades. For short distances, say, up to 300 ft., 7% grades may not necessarily be dangerous on the main highways, nor 9% grades on secondary highways. It should be kept in mind, however, that the same theory of relationship applies to grades as to curves. A steep grade will be much less dangerous if approaching lighter grades and curves have slowed down the speed. Thus, frequently, the steepest grades and sharpest curves are not the greatest source of danger.

#### COMBINED GRADES AND CURVES

Care should be taken in combining maximum grades and curves. If each alone is a source of danger, their occurrence on the same stretch of road is sure to increase the hazard. Hence, the combination of the steepest grade and sharpest curve on any road should always be avoided.

It is difficult to determine what compensating value should be assigned to curvature in conjunction with maximum grade. Perhaps it is not far wrong to assume that 5° of curvature may be equivalent to at least 1% of grade. In hilly or mountainous country, it is well to guard against the mistake (frequently made) of securing long uniform grades at the expense of sharp curves.

#### CROWN

The higher the crown the more dangerous is any pavement, especially on a rural highway where high speed prevails. Perhaps the effect is almost negligible up to 2 in. of crown in 18 ft. of width; however, on grades and curves any camber increases the danger to traffic. One should not be misled by the fact that the ordinary gravel and stone surface requires more crown on grades to prevent erosion of the surface and thus make the mistake of applying this same dangerous design to grades on pavements. Sometimes it is possible to carry the water down the slope on the pavement more cheaply than in the side ditches. In these cases the pavement itself should be widened 4 to 6 ft., at the same time narrowing the shoulder to a few feet with no side ditch, all water going down the pavement which should have curbs. This design in deep cuts will often save enough in excavation (to say nothing of future maintenance) to pay for the extra width of pavement. It necessitates spillways at the foot of the grade, but practically obviates the crown.

On a modern high type pavement there seems to be little excuse for using more than 1½ in. of crown in 18 ft. of width. A favorite highway warning sign is, "Dangerous When Wet". While the pavement may be on a light grade and of a type of surface which is more or less slippery when wet, the dangerous feature is greatly increased by the unnecessarily high crown. It may be difficult to prove absolutely the amount of additional danger due to the high crown; however, as there is no economy in such construction and little or no cost in eliminating it, the camber might just as well be kept to a minimum.

#### WIDTH OF PAVEMENT AND ROAD SHOULDERS

Exactly what effect the width of pavement may have on the safety of a highway is open to argument, because the wider the pavement, the higher

the speed; and speed is a factor of danger. From observation, however, it seems that although the wider pavement may invite a higher speed, it affords at the same time a net contribution to the increased safety of the highway.

The accident statistics of the National Road leading east out of Indianapolis, Ind. (a 30-ft. pavement), as compared with those on the 18-ft. pavement going westward out of the same city, are instructive. The traffic on these two roads should be about the same. There seems to be no evidence proving the claim so frequently made that a three-lane pavement is more dangerous than one of two lanes. Out of the fifteen accidents reported on the 30-ft. pavement all but two happened at intersections due to traffic driving on the wide pavement from the side roads or private drives. No serious injuries or great damage occurred. On the other hand, on the 18-ft. pavement there was one fatality, three pedestrians were seriously injured, and twelve turn-overs or collisions occurred, in which the occupants received minor injuries. These meager records point to greater safety on the three-lane pavement.

Wide shoulders properly maintained serve traffic in an emergency. On the 18-ft. country pavements a 6-ft. shoulder has been used as a standard. On heavily traveled roads an 8-ft. width certainly is desirable, particularly where fills are made with a 1 on 1.5 slope. Not only do these shoulders serve traffic in an emergency, avoiding an accident, but also as a parking place for changing tires, or other reasons. Numerous accidents are traceable to cars parked on country pavements and most States have laws prohibiting such practice. However, unless sufficiently wide shoulders are provided the practice of parking on the pavement will be difficult to control.

#### SUFFICIENT WIDTH OF RIGHT OF WAY

While heavily traveled roads are requiring wider pavements and wider roadbed, it is also imperative to provide sufficiently wide rights of way. Every tabulation of accidents shows a growing number of collisions with telephone poles and other appurtenances. For any important country road, 60 ft. should be the minimum width of right of way, poles being placed at the outer edge. Heavily traveled highways where unusually wide pavements are necessary, should have the needed additional width. There is no excuse for sitting by and permitting people to be killed by running into obstructions that should have been properly located, not only for safety, but to provide a more artistic appearance and room for roadside planting. That many a heavily traveled road with lines of high poles close to the traveled way looks like an alley, is no credit to the engineer or other official who may be responsible for this condition. Many States have the practice of securing 80 and even 100 ft. as a standard for their main State roads. Such widths are not practical through rich agricultural lands, but in the sparsely settled, low-valued districts, they are commendable.

#### SLIPPERY PAVEMENT SURFACES

It is well known that a slippery road surface contributes to accidents. One section of wood block pavement (about four squares) was so slippery,

due to the method of treatment, that one or more accidents occurred nearly every time the surface was wet; it was not uncommon to find three or four cars piled up after the beginning of a rain. Concrete and bituminous road surfaces are the most common pavements. Of the bituminous type, the bituminous macadam or surface-treated road is the most frequent in the rural districts. This type of road can be made into a less slippery surface by the proper grade and amount of bituminous treatment and of aggregate used for covering. On steep grades it is particularly desirable to spread a coating of 1-in. or 1½-in. stone during the last hot weather of the season.

Some concrete road surfaces are far more slippery than others. It is extremely desirable that some research work be carried on to determine what might be done to make the best non-skid type of surface for this pavement. A dry mix and proper finish may be used to reduce the slipperiness to a minimum. It is well known that the so-called "harsh mix" of concrete gives the opposite of the slippery surface sometimes found. To what extent this mix can be used without materially lowering the strength of the concrete should be determined, especially for grades where slipperiness is a big factor.

The oil dropped from motors adds greatly to the accident hazard. A wider pavement, by scattering the oil, aids in reducing the slipperiness. A sprinkling of cinders on such a surface also helps greatly.

#### DITCHES AND DITCH SLOPES ALONG THE HIGHWAY

As the wider shoulder serves in an emergency as a turnout, the inner ditch slope, if more flat, may permit a vehicle to go down and come out again without upsetting. If it is too steep it may be the source of many an accident. There seems to be little excuse for making these slopes steeper than 1 on 3.5. In addition, the flatter slopes are more economical to maintain because of lessened erosion and also the reduced cost of mowing the grass and weeds.

In past years deep ditches for drainage have been constructed along highways. One heavily traveled road paralleled by such a ditch for 4 miles has claimed five lives in 5 years. Another stretch (11 miles) shows a property loss to damaged vehicles of \$24 000 per year. The public as well as engineers should protest against the practice of a land owner deepening the road ditch in order to drain his farm.

#### RAILROAD CROSSINGS

*Approaches to Grade Crossings.*—Narrow highway approaches to railroad crossings often contribute to accidents. In one such instance four years after the approaches were widened not a single accident has been recorded, although previous to the widening, accidents were common. It is a psychological fact that if a driver's attention is occupied with one thing he cannot so well give it to another. Apparently, this was the only principle involving danger at this crossing. Some advocate a rough road surface at a crossing to slow the traffic and thus increase the safety. It is very likely that all the advantages in slowing down the traffic would be more than outweighed by the detraction of a driver's attention from an approaching train.

*Acute Angle of Approach.*—At one point in Indiana an acute angle between a main highway and a heavily traveled railroad has been the source of many

accidents, due to the wheels of vehicles catching in the groove alongside the rail. This angle (about  $15^{\circ}$ ) is entirely too sharp for safety. It is desirable if not too inconsistent with the alignment, to lay out such crossings at an angle greater than 25 degrees.

*Center Posts at Grade Crossings.*—At this same crossing center warning posts were erected with a view of reducing accidents. These center posts during the short time of their use, were the source of many times more accidents than they prevented. While such posts may be safe in cities on wide pavements where high speed is not common, they are hardly safe on a wide rural highway where high speed prevails and cannot be so well controlled. Doubtless they would cause many more accidents than the grade crossing itself. While the arrangement might shift the responsibility on the automobile driver instead of permitting the railroad company to take a share, it would not contribute to the safety of such crossings.

*Elimination of Railroad Grade Crossings.*—Grade crossings on all heavily traveled highways should be eliminated as rapidly as finances permit, either by relocating the roads or by building the necessary structures. Frequently, relocation is the cheaper and at the same time safer method. All structures are small sources of danger in themselves. As formerly built with sharp turns at the approaches, they served horse-drawn traffic fairly well; but with modern traffic such structures are a source of danger only lesser in degree than the grade crossing.

#### BRIDGE WIDTHS

While narrow roads take their toll, narrow bridges on heavily traveled roads are also a menace. Not only that; due to the frequency with which they are hit and damaged by traffic, in the end they may be more expensive than wider ones. On all important roads, structures of about 20-ft. span or less should carry the full width of the roadbed, that is, pavement plus shoulders. With large structures, because of the cost involved, some sacrifice must be made in safety to fit the treasury. It must also be recognized that any large conspicuous structure, such as a bridge, is more readily observed by a driver and far less apt to be hit than a smaller one, and hence does not need such a wide clearance. On roads designed to carry two lanes of traffic, the proper widths for medium large structures are at least the width of slab needed to carry the traffic plus 8 ft. for primary roads and 4 ft. for secondary roads.

#### ADVERTISEMENTS AND OTHER OBSTRUCTIONS

Any kind of a billboard or obstruction on the highway, which will detract from the driver's attention, is a contributing factor to accidents. For this reason, as well as for the sake of appearance, all advertisements should be eliminated from the right of way. In most States on the main highways this has been done; in some places, however, they have re-appeared on warning signs. Perhaps all the advantages of the sign are sacrificed by such practice. The habit of painting advertisements on the pavement should be stopped by imposing a severe penalty. Likewise, the method of erecting crosses along the highway where fatalities have occurred is of doubtful value.

## WARNING SIGNS

During recent years traffic has increased rapidly, out of proportion to the limited finances for coping with it. Hence, nearly every highway system in America has many dangerous places, some of which cannot be eliminated for years to come. The only recourse is to warn the traveler. Flashlight signals should be installed at practically every grade crossing of an important highway with a high-speed railroad. In Indiana (1927) there are 511 grade railroad crossings on the State Highway System and only about 100 of these are protected by watchmen, gates, or suitable flash signals. Of all fatalities reported on this System, 36% in 1925 and 25% in 1926 occurred at railroad grade crossings (Ohio records show about 30 per cent.). It seems impossible to reduce these fatalities without giving greater protection to the public at such places.

The State should protect the unsuspecting driver against all dangerous places in the highway with ample markers. A standard system for this purpose adopted by the American Association of State Officials seems to work satisfactorily. It should be adopted universally so that the traveler will not be confused by different systems in different States.

Safety campaigns through newspaper publicity have been waged throughout the nation to influence the motorist and thus bring about saner driving. Many people have felt discouraged because of the constantly increasing number of accidents and have concluded that these campaigns were of little value. The writer, on the contrary, believes the most valuable means of increasing safety on highways is to continue such campaigns. Because accidents have not decreased it does not follow that such campaigns have not been beneficial. The greater speeds of travel together with the increased number of vehicles are responsible.

The engineer's duty in the reduction of accidents is a very important one. Although the source of danger preventable by his work is limited, perhaps it can be more easily controlled than any other. The improvements in the automobile bring increases in the speed; the engineer must cope with this problem.

Much can yet be done. Little, however, can be accomplished without study and effort. It is far better to recognize this and put forth every effort to increase safety. The opposite attitude once was taken by a prominent official when he became disgusted with the high-speed traffic and "gave up" with the remark, "Let the damned fools kill themselves". Nothing is so hopeful as making an effort and this is the responsibility and duty to the general public owed by engineers.

## DISCUSSION

E. W. JAMES,\* M. AM. SOC. C. E.—There can be no possible doubt of the highway engineer's responsibility. The success with which critical danger points have been either wholly eliminated or reduced in hazard by a careful study of specific conditions, as, for instance, in the State of Maryland, establishes beyond question that certain features of highway design and construction are responsible in many cases for the accumulation of accidents, and also that the correction of these conditions may be relied upon to provide considerable remedy.

Mr. Hinkle has not touched upon this detail in a general way and it deserves attention. When Maryland first began collecting accident records, the ordinary wall map with pins to locate the accidents as they occurred, was used. In the course of the report the pins accumulated in significant clusters. The engineers of the State Highway Department made a careful study of each of these dangerous points and without knowing the details of the accidents they were able to find conditions which obviously needed correction. Whether they found all the conditions, both major and minor, which were responsible for the accidents makes no difference. The work done in the way of flattening curves, superelevation, widening, clearing the line of sight, etc., served to reduce the number of accidents at such points significantly. This is obviously the first and simplest method of attacking the accident problem in so far as the reconditioning of existing roads is concerned.

It is obvious that there still will remain scattered accidents, more or less well distributed over the highway system, but to what extent the engineer is responsible for such accidents is more difficult of determination.

The Association of State Highway Officials has recommended that all States adopt the form of accident report used by the National Safety Council. This report, if used, will disclose some of the miscellaneous causes of scattered accidents. A study of the annual record will indicate corrections that may be necessary where clustered accidents do not occur.

One of the important points in the paper appears to be the relativity of dangerous conditions. The combining of sharp curvature and long tangents is an example of this when compared with a road in a mountainous area in which there is considerable sharp curvature with no long connecting tangents. In the first condition the sharp curve is unquestionably more dangerous than in the second condition. Another important point is the avoidance of a combination of bad conditions. As an example, maximum curvature and maximum gradient should not be combined.

Mr. Hinkle mentions a considerable number of design details which have relation to existing hazardous conditions, and attention should be drawn to the two classifications into which these details may be grouped. There is one group susceptible of approximately uniform treatment. In this are width of traffic lane, minimum radius of curvature, maximum gradient, maximum crown, superelevation, easement, widening on curves, and width of shoulders.

\* Chf., Div. of Design, U. S. Bureau of Public Roads, Washington, D. C.

There are other features which are not susceptible to uniform treatment, but among which definite relations may be established. For instance, the succession of curvature, as Mr. Hinkle shows, is likely to affect the safety of the highway where long, easy curves have sharp curves unexpectedly introduced. Sharp curvature on steep grades is more dangerous than in combination with low grades; and sight distance, where highway conditions induce high speed, should be adjusted on both horizontal and vertical curves to favor the traveler.

Just what values shall be assigned to those details which are subject to uniform treatment are still matters of discussion, but there seems to be a marked drift of opinion toward certain values. The Association of State Highway Officials has recommended a width of 10 ft. for each traffic lane as a standard of practice, and this is in harmony with the report of the Hoover Conference on Street and Highway Safety. The speaker suspects that if the comparison made by Mr. Hinkle between the three-lane 30-ft. road out of Indianapolis, Ind., and the two-lane 18-ft. road out of the same city had been made between a 30-ft. road and a 20-ft. road, respectively, the relative number of accidents would not be so markedly against the two-lane road. With the speeds which are common on the public highways to-day, an 18-ft. two-lane road lacks an element of safety which can probably be provided by an additional 2 ft. of width.

The width of shoulder is likewise a detail which can be given general treatment. The Association of State Highway Officials has recommended a minimum width of 8 ft. This will allow ample space for the installation of the necessary markers and caution signs along the shoulders, and will provide space for parking cars, thus removing the inevitable element of danger and interference with traffic which results from parking cars on the surface of the road.

The values to be given maximum gradient will depend to a considerable extent on the general topographic conditions existing, but it is a significant fact that on new roads constructed in the Rocky and Sierra Mountains better gradients have been secured than exists on many of the old established roads in the Appalachian System. This rather effectively disposes of the contention that extreme mountainous conditions demand large concessions in the matter of maximum grades. Perhaps some concession is necessary, but it is probably very slight in any case. It is probable that on main highways a maximum grade of 6% can be secured anywhere in the United States without unduly increasing the cost of construction. It is clear, however, that reduction of grades to this figure on the old established highways in the East cannot be made without substantial relocation and the virtual construction of new roads. The speaker believes that this will eventually happen, and that the main route through Southern Pennsylvania between Philadelphia and Pittsburgh, the old National Road through Cumberland, Md., and others, which are well known and heavily traveled by through traffic, will eventually be replaced by roads of substantially lower gradient. It is significant that the old Northwest Turnpike passing through Winchester, Va., and crossing the Appalachian Mountains to Romney, W. Va., which was laid out by Crozet when

he was State Engineer of Virginia, has a maximum gradient of 7%, whereas 10% grades occur on the road in Pennsylvania, and the standard maximum on the National Pike is 9 per cent.

What value shall be given to permissible lengths of different gradients? This is a question which might well be investigated in detail either by the highway engineer or by the designer of motor vehicles. For instance, in the manual\* for the erection of caution signs, which has been adopted by practically all States, there is a recommendation to erect a sign advising the traveler to shift gears at the top of a certain grade. The sign should ordinarily be used under the following conditions:

On a	6%	grade,	more	than	2 000	ft.	long.
"	"	7%	"	"	"	1 000	"
"	"	8%	"	"	"	750	"
"	"	9%	"	"	"	500	"
"	"	11%	"	"	"	400	"
"	"	13%	"	"	"	300	"
"	"	15%	"	"	"	200	"
"	"	16%	"	"	"		"

Obviously, the high gradients appearing in this tabulation have reference to grades on existing roads, because no such grade would ever be designed by a highway engineer to-day; but it is probable that grades of 7 and 8% will continue to be used on secondary roads, and the capacity of the brakes of a motor vehicle to hold the car without themselves burning should be studied to determine the lengths of the several gradients which it is safe to build under existing practice in motor-vehicle construction.

Mr. Hinkle also refers to the widening of pavement at dangerous intersections. The whole subject of highway intersections is up for general review and unquestionably a variety of solutions will have to be adopted, depending on the conditions of traffic found to exist and on the topographic situation in the immediate vicinity. It is an obvious fact that if the traffic on two intersecting highways is up to the capacity of both continuously, or at the daily peak periods, those roads at such times are only 50% efficient. Eliminating highway grade crossings entirely would at once raise this combined efficiency to 100%, but such substantial improvement can only be made where the traffic is very heavy on both routes.

Probably the next most favorable treatment for such conditions is the use of the rotary intersection. This is a detail of highway design which deserves close analysis and study. It is by no means a panacea, but it unquestionably increases the efficiency of an intersection at grade where traffic is heavy, and it is relatively inexpensive. The capacity of such a rotary intersection is probably a function of the radius of the center line of the circular pavement and of the number of routes delivering traffic to the intersection. Theoretically, the width of the circular pavement should be 25% of the sum of the width of all radiating roads. There are not a great many of these rotary

\* "Manual and Specifications for the Manufacture, Display and Erection of U. S. Standard Road Markers and Signs," Wash., January, 1927.

intersections in existence, but where they have been used, the success of their operations in handling the large traffic flow certainly warrants further investigation and probably a considerable extension of their use.

Where rotary intersections are not possible, Mr. Hinkle offers a solution which is simple and apparently effective within certain limits. It should be observed, however, in connection with such widening that it does not serve greatly to increase the efficiency of the intersection and is valuable principally as a detail of safe construction. For instance, widened pavement may call attention to a dangerous intersection, but it will only shorten the line of traffic which is forced to stop by the small number of cars that can crowd into the additional width of pavement at the point of stoppage. Such widening might be advantageous at railroad crossings where it would be an indication of a dangerous condition and also permit a slightly greater freedom of manipulation by the driver in case he has to stop suddenly or swerve to one side to prevent accident.

This widening of pavement, as described by Mr. Hinkle, has a rather interesting limitation which once came to the speaker's attention in connection with a design submitted by one of the States on a Federal Aid project. The proposed treatment of an intersection involved a circular connection in each of its four quadrants and a radius of about 800 ft. was used for these curves. The result was a geometrical pattern in which the original intersection had to be left for direct traffic on the two routes and the circular curves, amounting to a total of 360° with all the right of way involved, were introduced merely to take care of that part of the traffic which turned from one intersecting road to the other. Had the entire area within the curves been paved in the form of a widened intersection, it would have been almost as capacious as a small city square.

Finally, the speaker wishes to call attention to the fact that it will be almost impossible to eliminate all dangerous conditions existing on roads now constructed and in service. Whatever engineers may do in new design and in reconditioning, it will be many years before State Highway systems, even on main routes, will be entirely free from objectionable or even dangerous details. Where these exist, the simplest duty of the highway engineer is to inform the public pointedly and timely of the conditions present, and give the driver warning that he is to take care of himself. The standard warning and caution signs adopted by the Association of State Highway Officials are, apparently, very effective in this respect. Public comments favorable to their use have already been received, and requests to extend their introduction have been made in some instances.

A broad study of the conditions producing accidents cannot be made for rural highways to-day. At best, only a few States are obtaining adequate data as to highway accidents. Such studies are likely to be extended, however, and as rapidly as the highway engineer has information, it should be analyzed and its results developed in the details of highway design at every possible point of application.

LOUIS P. BLUM,\* M. Am. Soc. C. E.—It frequently happens that the test of the carrying capacity of roads in this country occurs on such holidays as Labor

\* Civ. and Min. Engr., Pittsburgh, Pa.

Day. It would be instructive to have a record of such unusual traffic movements as compared with Sunday or other holidays. It is hoped that if the Ohio Transport Survey has such data they will be made available.

Engineers do not place sufficient emphasis on the necessity of properly, systematically, and regularly posting roads with uniform signs. On railroads, there is no question that the adoption of a uniform system of signals to effect a uniform purpose has produced great results in the matter of saving lives. In the bituminous district of Western Pennsylvania, at the insistence of the insurance companies, the same sign printed in exactly the same manner conveys the same meaning in every mine.

Now, why should not the same uniformity prevail with reference to road signs? There is no more urgent need than this. States, counties, and cities seem to vie with each other in an endeavor to produce highway signs in the greatest variety of style and location. In one of the principal cities of Pennsylvania along the William Penn Highway there are three red lights at three intersecting corners; one of them is on the right side as the driver approaches it; the next one is in the center of the street; and the next one is over on the left side.

Is there any logical reason why, as the driver passes over the State line from Pennsylvania to Ohio, he should find railroad crossings marked in an entirely different manner? Is there any logical reason why a road crossing should be stated in Pennsylvania as being a "road crossing" and in Ohio an "intersection"?

The suggestion has been made that certain highways in the cities should be called "arterial roads."\* While this means something to the engineer and to the educated man, it may fail to convey its safety message to the ordinary, uneducated driver seeking to thread his way through the maze of traffic of a strange city.

Mr. Hinkle has well said that "if a driver's attention is occupied with one thing he cannot so well give it to another", and it seems to the speaker that highway safety demands the adoption of an absolutely uniform system of signals throughout the United States—uniform as to shape and color.

C. N. HAGGART,† ASSOC. M. AM. SOC. C. E.—In driving over various highways, the speaker has noticed that drivers occasionally take the inside of the curve in making a left-hand turn. Would it not be good engineering and designing for safety, to increase the superelevation on the outside of the curve and thus encourage drivers to keep to the right side of the road? In some places, the outside of the curve looks very dangerous, particularly for making a left turn on a down grade, with a steep declivity to the right. Even a cautious driver may be tempted to drive to the inside of the curve under such conditions.

It is the speaker's understanding that the Bronx Parkway Commission of New York has a standard of design similar to this; the only difference being that the superelevation between the inside and outside lanes of traffic is

\* *American City*, December, 1927, p. 761.

† Structural Engr., Pittsburgh, Pa.

decreased. As far as is known, this method of superelevation has proved very satisfactory on the Parkway. The idea might be well worth investigating for the sake of safety on the highways.

H. J. KIRK,\* Esq.—In connection with superelevations, it is well to keep in mind that conditions vary on a rural highway as compared with cities and villages. The superelevation is a function of speed in the vehicle and it must be remembered that on rural highways there is a mixed traffic and that it is possible to make the superelevation so high that trucks are inconvenienced by it, particularly in winter when the highway is covered with ice. This complaint has been made on some highways that carry heavy truck traffic. The superelevation is fine for motor cars, but it seriously inconveniences some of the heavy trucks because they cannot maintain the speed necessary for that superelevation.

There have recently appeared some advocates of a so-called rotary intersection. Theoretically, this appears to be very fine, but it is not practicable where there is any amount of pedestrian traffic. It is noteworthy that where these intersections have been tried in Columbus, Ohio, they have been abolished.

W. W. CROSBY,† M. A. M. Soc. C. E. (by letter).—It seems to the writer that Mr. Hinkle has performed a signal service by analyzing the situation and pointing out so forcefully the duties of the engineer.

It may be necessary, in order to bring home to Americans the realities of a situation, to personalize the matter of safety and to emphasize or dilate on the financial costs of accidents to individuals as has so often and so generally been broadcast in recent years. In countries where highway problems are older and often better comprehended, the safety of the individual is subordinated to the safety and continuity of the traffic as a whole. Thus, the problems may be approached with less hysteria and with calmer judgments exactly as Mr. Hinkle has tried so well to meet them.

Under the head of "Widening on Curves", the remarks made seem logical, although the writer cannot agree to any deduction that "spiraling" should not be used on "highway curves".‡

Although Mr. Hinkle did not list "Advertisements and Signs" among the causes of accidents for which the engineer may properly be held directly or indirectly responsible (according to his actual authority), they are mentioned pertinently near the end of the paper.

The writer thinks there are, on the whole, and certainly often, too many signs along the highway. "Wolf! Wolf!" is cried too often with the traditional effect. So-called "informative signs" obscure the vision, distract the attention, and impair the caution of the drivers unprofitably. These all certainly fall within the scope of the engineer.

When it comes to advertising signs, of the same or worse consequence, words fail to express the situation adequately. The writer firmly believes that no advertising signs should be permitted within 200 ft. of the highway except

\* Director of Highways, State Dept. of Highways, Columbus, Ohio.

† Cons. Engr., Coronado, Calif.

‡ "Road Corners and Junctions," by Rees Jeffreys, Chairman, Roads Improvement Assoc. of Great Britain, *Municipal Journal and Public Works Engineer* (Lond.), January 6, 1928.

for business done on the premises, and then only under the approval (as to location, size, and type or form) of the highway authorities. In built-up sections, of course, the rule would have to be modified.

The writer confesses to a sympathy with the "prominent official", quoted in the author's last paragraph, when the eccentricities of a few drivers, or the "peaks" of average driving, run too far outside a reasonable "load curve" for safe use of well-designed highways. The engineer may well be ambitious to offer remedies for public benefit, but he may equally well refrain from going too far in attempting to insure the survival of the unfit. Some persons, in the exercise of their undeniable rights, may prefer to "die with their boots on" a throttle, and the engineer, like others, may do best by "sticking to his last".

VICTOR A. ENDERSBY,\* M. AM. SOC. C. E. (by letter).—This subject is one of increasingly vital importance to all highway engineers. Safety is now as important on highways as it ever was on railroads. It is continually more difficult to attain, and there is a marked increase in the public tendency to blame mishaps on the engineer. More than that, members of the public are becoming so familiar with the possibilities of engineering, that they can criticize lapses with hitherto unknown accuracy and lack of diffidence.

As Mr. Hinkle remarks, no exact line can be drawn. One can place a finger on a given set of circumstances and say "reckless driving", and upon another and say "bad engineering", with considerable certainty. The line lies at an indefinite location between, so that there will probably never be a legal definition of it.

The author, however, states that "about 30% of all accidents recorded in Indiana in 1926 were due to highway conditions". How can the figure be so definite? To say that any accident is due to "highway conditions" without qualifications is to say that no driver could pass that point without an accident. Driver responsibility cannot be eliminated from any accident; engineering responsibility can be reduced to an infinitesimal. Engineers and drivers both need education, but the handling of the latter is the more difficult.

*Alignment and Grades on Bridges.*—Bad grades or lines are more definitely localized and noticeable at bridges than elsewhere. The effect is made more acute by the fact that most bridges are narrower than the roadbed.

The State of California has inherited a vast number of bridges built on the ancient principle of crossing the stream (or railroad track) at right angles, and torturing the line to conform to it. This is a twin to the idea that, since bridges are few and far between, it is no hardship for traffic to slow down for an occasional narrow "gut"; hence, there are numerous bridges only 18 or 20 ft. wide, on main lines. The first fallacy has resulted in numbers of bridges on atrocious alignment, lying in wait to catch the driver lulled into a false sense of security by a long stretch of wide, straight, modern highway. The second forces the constant meeting and passing of machines on bridges too narrow for safety, and, in some cases, chokes the traffic to an actual standstill.

\* Constr. Engr., Bridges, Southern Section, State Div. of Highways, Los Angeles, Calif.

The bridge-building program of California is years behind the highway development, for reasons not within the scope of this discussion; and although the entire State Administration is anxious to remove this condition as fast as humanly possible, it will be years before it is wholly remedied. The contrast of some of the bridges with the highways leading to them has to be seen to be appreciated.

One definite step toward improvement can be taken by nearly any organization responsible for bridges; a step which at least will prevent the condition from becoming worse; that is, a policy of no compromise with bad alignment and narrow widths. Bridges should be subordinated to roads, not the reverse. If the funds are not available with which to build a bridge properly, the building should be deferred until they are, barring actually desperate conditions. This is the present working policy of California and it is justified both morally and economically. If a bridge is built which will merely better the traffic conditions slightly, it will have to be rebuilt sooner or later at great cost, meantime remaining a public danger. If the situation is serious, and funds are limited, it is better to build a structure of cheap materials on good line and grade, than a permanent structure which will have to be altered or superseded. Experience in California has shown that the life of a concrete bridge, if it is a little too narrow or on line a little too crooked, is so short that a wooden bridge on proper location will outlive it.

It is astonishing how many existing bridge alignments could have been bettered with little or no additional cost, by an intelligent study of topography and competent selection of design.

There are four common faults: First, the conventional practice of going around hills rather than through or over them (without due investigation of comparative costs); second, locating engineers allowing themselves to be bluffed by topography which looks formidable; third, unfamiliarity with the relative economy of types of construction; and, fourth, insufficient analysis of relative costs of piers and superstructure.

Again and again bridges are built at right angles to save length, where a longer bridge of another type could have been built on good alignment for the same money. All this would seem merely engineering platitudes, except for the fact that they are often neglected in unexpected quarters.

*Widths of Bridges.*—Present California practice (1928) is to use multiples of traffic lanes 10 ft. wide, plus 2 ft. on each side, the additional 2 ft. being omitted where there is a sidewalk. The widths are thus 24 ft., 34 ft., 44 ft., etc., except where special conditions require other widths. Mr. Hinkle's 8 ft. as against California's 4 ft. is, of course, an improvement, and is probably desirable where there are less than three lanes. Where there are three lanes, or more, it is not so important.

Bridges less than 34 ft. wide are becoming obsolete on California State Highways. One bridge is being constructed 100 ft. wide, and another, several hundred feet long, is being widened to more than 60 ft. Frequently, bridges 44 ft. and 34 ft. wide are built on 20-ft. pavements, a reversal of former practice. The apprehension as to such bridges is not that they will be too wide, but that they will be too narrow within a few years; but there is a limit to

which the public will permit the expenditure for wide bridges on narrow pavements.

*Railroad Crossings.*—There is no such thing as a good grade crossing. In California all railroad crossings are to be eliminated where possible and are tolerated only under duress elsewhere. Consideration of their relative danger enters the State policy only as a matter of deciding which shall be eliminated first with the use of funds that will always be insufficient, however large in absolute figures.

This is a difficult decision, although one which constantly has to be made. Charles E. Andrew, M. Am. Soc. C. E., Bridge Engineer for the State, has suggested that a formula could be developed giving reasonable mathematical values to the various danger factors, and that crossings could thus be set up for elimination by a mathematically rational method. The problem, however, is so involved that no one has made much progress with it. Meanwhile, California has so many bad crossings that no money is in danger of being spent on needless eliminations for years to come.

*Superelevations on Roads.*—All curves on California highways of less than 1500 ft. radius are now built with superelevations. Mr. Hinkle suggests that superelevations steep enough to cause sliding to the inside under ice conditions, could be taken care of by the use of a flat inner shoulder. The writer regards that suggestion as dangerous.

If there is real danger from this source, the superelevation should be reduced. Except where the bank is very high or precipitous, it is not as dangerous to skid off the outside as to encounter another machine on the "blind" side while out of control.

*Reduction of Curvature.*—The suggestion that the sharpness of a curve be limited with relation to that of the last one preceding it is a valuable one which will be endorsed by most experienced engineer drivers. The writer is familiar with situations where this would have saved much loss of life and property. It would seem that where a long stretch of easy alignment breaks into country where sharp curves are inevitable, considerable expense would be justified in the gradual reduction of radius for the first mile or so. Has this ever been tried?

*Widening.*—Some widening, to take care of the greater difficulty of steering and the traffic situations peculiar to curves, seems desirable. Beyond a certain point, however, widening on the inside is merely equivalent to a reduction of the curvature, owing to the tendency of machines to crowd to the inside. Mr. Hinkle's figure of 0.3 times the sharpness of the curve, in degrees, giving 1.5 ft. for a 5° curve, and 3.0 ft. for a 10° curve, seems more reasonable for the latter than for the former. Driving around a 5° curve is little more difficult than driving on a tangent. How was this formula derived?

There is, for standard machines, a certain critical curvature for each speed; on curves sharper than this, a widening of even 2 or 3 ft. on the inside produces an astonishing difference in safety of driving. Sharp curves on California highways are being progressively reduced by cutting back and adding oiled gravel shoulders in the course of maintenance work. It seems desirable

to make studies to determine the best minimum curvature for prevailing conditions—with a due allowance for future "improvements" in the speed of vehicles.

Considerable safety can be added by cutting back the slope on curves, leaving a berm about 4 ft. high over which the driver can see coming machines; the remaining bank keeps him on the original alignment.

Rough spots are more serious on curves than on tangents. A bump which would not matter in the latter case, will break tire traction and cause a skid in the former, owing to centrifugal force.

*Crowning.*—There is no longer a reason for crowns of more than 2 or 3 in. in 20 ft., except for dirt roads. California State highway pavements are crowned slightly to prevent water standing on the surface. Parabolic crowns were abandoned some time ago, the cross-section now being two straight lines. This makes for safe driving and easy steering. Some counties build pavement with no crown, but with a tilt of  $\frac{1}{2}$  in. to 1 in. for drainage. From some points of view this seems even more desirable, because drainage needs to be handled on only one side of the road at a time. There seems little logical reason for crowning on superelevations.

*Pavement Edges.*—It is a practical impossibility to maintain perfect shoulders on all concrete pavements; ruts form at the side. When machines run off the pavement, or are forced off, they cannot be brought back without a severe wrench, and if they are going at any great rate of speed, they may come back so nearly out of control as to weave across the road. This is a prolific source of accidents. Beveling the edge of the pavement sufficiently to permit the tire to climb it without a jolt might be advisable; it would certainly postpone raveling.

*Grades and Curves.*—The writer agrees with what is said about grades and curves. Mr. Hinkle, however, does not mention the effect of grades in slowing down trucks and thus congesting traffic. It would be well if the grades which cause the average truck to shift gear could be determined, and avoided on critical points, such as blind curves. Sometimes a long stretch of good grade is interrupted by a short piece of steep grade where climbing trucks can be depended upon to "bottleneck" the whole stretch. In general, alignment should never be sacrificed to grade from the safety point of view. Economically, the consideration tends to the other extreme, especially for slow heavy traffic.

*Traffic Separation.*—The writer believes that the day is in sight when freight traffic will be increasingly separated from light car traffic, on roads of its own. This will bring about two distinct standards of highway engineering, not only as to alignment, but as to pavement and bridge construction. Observation of traffic conditions in Southern California leads one to believe it impossible that public patience will tolerate the present awkward mixing for many more years. The attempt to handle hundreds of freight vehicles, including trucks and trailers with a combined length up to 50 ft. and a weight of 30 tons, over the same two-track road with large-volume light-car traffic, is simply foolish.

It seems inevitable that major highways of the future will be four-line; there will be center lines for through traffic with no upper speed limit, but with minimum speed at 30 or 40 miles, and side tracks for local and slow traffic.

*Width and Safety.*—Without doubt width contributes to safety. The cause of most accidents is the inability of the driver to maneuver, or to maneuver in time. On a wide road he not only has room to handle the machine and enough space to see what is transpiring ahead, but machines also tend to keep away from one another.

*Rights of Way.*—The standard width was 60 ft. when the original system of California State highways was laid out in 1912. The people of the State are now paying dearly for this, because of the necessity of getting 80 and 100-ft. rights of way through, not merely rich agricultural land, but miles of country which, although unincorporated, is urban in character. The minimum legal width is now 80 ft.

It is difficult to understand why narrow rights of way should ever be tolerated. In thickly populated districts the time to get wide rights of way is as soon as possible before values rise; in the country, the additional cost is low—and no one knows how long it will remain so.

*Advertisements.*—Signs are forbidden within the rights of way of California State highways. Unfortunately, however, much pavement is built practically up to the right-of-way line in just the locations where signs are thickest; that is, in the semi-urban districts. There is need for legislation forcing signs to be placed a definite distance back from the right of way, and also to prevent them from being placed in fields so as to cut off the view of the road ahead, or of tracks in case of crossings.

The tendency of "hot dog" stands, service stations, etc., to be crowded as close as possible to the right of way along country roads, thereby converting these roads for all practical purposes into city streets, are evils of a similar nature. Not more than one-half these obstructions pay their way, and it would be to the good of humanity if some means could be found, not only to force set-backs, but to eliminate a large percentage of the buildings altogether.

*Pedestrian Traffic.*—California highways are lined with pilgrims of all descriptions, young and old, who walk on the pavement, signal motorists for rides, and often shout at them. They force the driver to swerve into the center of the road, frequently distract his attention from his driving, and check and endanger traffic by causing machines to stop to pick them up. Legislation is proposed to make it a misdemeanor to walk anywhere except on the left-hand side of the road. This would help in so far as it is enforced.

*Warning Signs.*—The writer has not much faith in warning signs as now used. He is rather inclined to think that drivers who are careful enough to notice ordinary signs will take care of themselves anyway, always excepting cases where the road presents dangers not normally to be expected, such as a sudden sharp turn at a bridge, etc. On bridges under construction, detour signs the size of a house, well lighted, are constantly being driven into and knocked into kindling wood. One driver passed three red-and-white, "Danger—Bridge Out" signs, 4 by 6 ft., spaced several hundred feet apart; he wrecked three out of five red lanterns, all burning, and smashed an 8 by 10-ft. detour

sign with 5-in. red reflectors. When he was pulled out of the wreckage, he wanted to know why the "blank-blanks didn't have some lights out". He was not drunk.

No means of warning the public should be neglected; but warning signs are by no means substitutes for safety engineering. Great care should be used in placing signs. On California highways, there are too many warnings of curves ahead, placed without much regard to the relative danger of the various situations. The same sign is used to notify of curves which can be driven at 40 miles, and those which are death-traps at 25 miles. Drivers become accustomed to disregarding signs and using their own judgment. Warning signs should be used sparingly, only where real danger exists, and then should be made as prominent and emphatic as possible.

Money spent on signs, carefully considered and designed, could be saved by the elimination of a great number of ineffective ones. There is a crying need for extended psychological study in this field.

*Education.*—Education can do much, but it cannot alter eyesight, machine-sense, or speed of reaction. It can partly eliminate mental carelessness, but cannot level the discrepancy between machine power and flesh and blood. The best driver can hardly get the brakes on in less than  $\frac{1}{2}$  sec. after sighting an unexpected danger. This is nearly 30 ft. at 40 miles per hour, and a highly fatal distance under many circumstances, to say nothing of the time required to stop after that. Every one curses the habitual fools; but hardly any one can say that he does not drop to their level upon occasion, through weariness, temporary nerve depletion, abstraction, or sheer ennui. The automobile has created a schedule of living which necessitates fatalities as absolutely as does the staking of flesh against machinery in war. The engineer cannot hope to catch up with the development of the automobile, but he can save lives, by pushing his methods of construction everywhere possible over the narrow margin between safety and destruction for the average driver.

G. C. DILLMAN,\* M. Am. Soc. C. E. (by letter).—A review of the paper indicates that Mr. Hinkle has covered this subject in a very complete and able manner. The writer agrees that the highway engineer is responsible for highway safety to the extent of the design, construction, and maintenance of highways, and that it is the highway engineer's duty to "keep abreast" with all modern developments pointing to increased traffic study. The limits set by Mr. Hinkle relative to sight distance, degree of curve, widening and super-elevation of curve, allowable grades, and his treatment of the railroad-crossing problem, all represent sound engineering practice.

In connection with statements on widths of pavement, the writer believes that 20 ft. is the best standard minimum width for main highways, and that when traffic demands an increased width, it should be 40 ft. rather than to 30 ft. In other words, the road surface should be such as to accommodate either two or four lanes of traffic, and the three-lane surface should be avoided if possible.

---

\* State Highway Commr., State Highway Dept., Lansing, Mich.

In connection with shoulder widths the writer would fix 8 ft. as the minimum width for main highways as being none too wide to accommodate the parking of a truck for repairs. Shoulders should be maintained in such condition as to permit traffic to turn out on them safely in emergencies, and to park on them for repairs.

The writer believes that 100 ft. should be the minimum width of right of way for all main highways, and that in cases of very heavy traffic on roads adjacent to large cities the right of way should be 150 to 200 ft. wide. While this might appear to be extravagant, in some cases, if the adjacent property is very valuable or highly developed, it is probable that this property will increase in value and that money will be saved ultimately by purchasing the necessary land now. Ample right of way is one of the chief requisites for future safety developments.

Mr. Hinkle's comments on the necessity of avoiding the construction of highway surfaces of a slippery type, or the use of maintenance methods which promote a slippery surface, are very heartily endorsed. The practice of sanding icy pavements, particularly on grades and curves, is suggested by the writer as good maintenance practice.

The widening of approaches to railroad grade crossings is very desirable, and such improvements should also contemplate the increase of a clear view at such crossings. An attempt is made in Michigan to create a clear view on highways between the driver of a car 300 ft. from the crossing on the highway and the train 600 ft. from the crossing on the railroad. This triangle, if possible, should be kept clear of buildings, trees, brush, or farm crops other than low growing varieties. Condemnation of such property is believed to be warranted if it cannot be purchased otherwise. It is thought desirable to have the angle between a railroad and highway not less than  $45^{\circ}$ , and preferably  $60^{\circ}$ , in order to give the motorist a better view of approaching trains.

Narrow bridges are a distinct menace to traffic, and every effort should be made to have all culverts and small-span bridges constructed to the full width of the highway grade. Mr. Hinkle's point that bridges of longer span are more conspicuous and usually promote more cautious driving than smaller bridges, is well taken. The maintenance of bridge floors and railings is an important item in safety to traffic, and it is highly desirable that any bridges which are not capable of bearing full loadings should be posted, with the safe load limit indicated. Thorough inspection of all bridges twice a year should be standard practice.

The construction of "by-pass" routes to carry through traffic around congested cities rather than through business sections is a feature of highway work which promotes not only safety, but convenience of traffic. In suburban areas, where there is considerable pedestrian traffic on highways, it is highly desirable to provide footpaths back of the ditch lines. All highway bridges in such areas should include sidewalks. The construction of pedestrian tunnels underneath heavily traveled roads is an important safety measure, particularly in the vicinity of school houses.

Ample guard-rail protection on high fills is very desirable. The old type of wooden guard rail is a distinct hazard in modern traffic, as many fatal

accidents have occurred when cars, striking wooden rails, have had sections of rail pass through the radiator or wind-shield. Cable guard rail is considered preferable to wooden rail, not only from the standpoint of safety, but because it does not drift snow on the roadway like the wooden rail.

Careful attention should be given to the maintenance of gravel roads with reference to the elimination of the two traffic hazards, loose gravel and dust. The use of some dust palliative, such as calcium chloride or light oil, is a prime requisite under modern traffic conditions. Sufficient binder material should be placed on gravel roads to bind the loose gravel, or, if this is impracticable, the excess loose gravel should be carried on the edge of the roadway during the heavy traffic season and brought back into the roadway in the fall where it will tend to consolidate into the road under fall rains.

The careful selection and maintenance of detours with a view to minimizing traffic hazards is receiving increased attention from highway engineers every year. The winter maintenance of highways should provide sufficient patrol of the surface to avoid dangerous ruts in the snow.

A class of highway traffic which has developed rapidly is the moving of large equipment, such as steam shovels, concrete mixers, etc., on large trailers. Movements of this kind should be allowed only under special written permit from the highway authorities in charge, in order to afford proper protection against destruction of roads and bridges, and to safeguard other traffic while it is passing this oversized load. Movements of this kind should be confined to daylight hours, as a vehicle of this size is a distinct menace to other traffic at night.

The engineer should make an intelligent study of the causes of traffic accidents and develop a systematic practice for increasing the safety of the roads. This may be brought about through traffic surveys and research, more adequate road design and construction, better maintenance, pavement markings, and the installation of signs and signal devices. Standardization is a prerequisite to safe traffic conditions, and the engineer is in a position to exert much influence in the standardization of engineering features and the development of traffic regulations which should be uniform in character.

### THE SEWAGE DISPOSAL WORKS OF DECATUR, ILLINOIS\*

BY SAMUEL A. GREELEY,† M. AM. SOC. C. E.,  
AND WILLIAM D. HATFIELD,‡ ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. GEORGE W. FULLER, JOHN F. SKINNER, AND  
SAMUEL A. GREELEY AND WILLIAM D. HATFIELD

#### SYNOPSIS

Since 1917 the Sanitary District of Decatur, Ill., has completed intercepting sewers, pumping stations, and treatment works for sewage disposal at a total cost for construction projects of about \$1 700 000. The treatment of the sewage has been complicated by the waste from a large starch works which has increased the human population of about 50 000 to a total equivalent population of 300 000, more or less, during periods of heavy corn grinding at the starch works. The peculiar character of the sewage has required the operation of two testing stations prior to the design of the sewage treatment works. A record of the steps taken and of the works built in connection with the development of this project is described in this paper. The writers' connections with the work were as Consulting Engineer and Superintendent, respectively, for the Decatur Sanitary District.

#### GENERAL STATEMENT

*The Problem and the Work Done.*—For a year or so prior to 1912, the pollution of the Sangamon River below Decatur, Ill., was sufficiently marked to arouse complaint and the situation was brought before the Rivers and Lakes

\* Presented at the meeting of the Sanitary Engineering Division, Columbus, Ohio, October 13, 1927.

† (Pearse, Greeley & Hansen), Chicago, Ill.

‡ Supt., Sewage Disposal Plant, Decatur, Ill.

Commission, which had jurisdiction over stream pollution in Illinois at that time. The city had a population of about 35 000 and included among its industries a starch works with a daily grind of 5 000 to 10 000 bushels of corn. The sewage from the starch works had a relatively high population equivalent and it was soon recognized that special study would be required to determine the most suitable method of treatment. All the existing sewers were combined, with four main outlets into the river below a low channel dam at the water-works (Fig. 1). For several months nearly every year, almost the entire flow of the river was diverted to the water supply and discharged again into the river as sewage. Thus, an increased water supply through storage on the river was indicated.

Projects for intercepting sewers and sewage treatment were developed in 1915 with an estimated cost of \$730 000. This relatively high sum made financing difficult, so that ways and means were carefully studied by city officials and citizens' committees. As a result, the Sanitary District Act of 1917\* was prepared and passed by the Legislature. All the construction work for sewage disposal has been done under this Act, amounting all told to nearly \$1 700 000. The city has since grown to about 50 000 inhabitants and the grind of the starch works to as much as 45 000 bushels in 24 hours.

The work done may be briefly summarized as follows:

(a) The necessary field surveys and office studies for the determination of intercepting sewer and sewage treatment projects.

(b) The operation of two testing stations. One comprised an Imhoff tank and sprinkling filter to determine the behavior of the mixed domestic and industrial sewage. This station was operated in 1914 and again in 1917. The other comprised a tank with a Simplex surface aerator for studying the partial or pre-aeration of the Imhoff tank effluent before applying it to sprinkling filters at the main sewage treatment plant. This work was done during 1925 and 1926.

(c) The construction of an intercepting sewer 18 317 ft. long and a sewage treatment plant comprising a grit chamber, six Imhoff tanks, sludge-drying beds, six pre-aeration tanks, two settling tanks for aerated Imhoff tank effluent, 3 acres of sprinkling filters, one final settling tank, and appurtenances. There are two small pumping stations for low-level districts. Actual construction work was started in 1919 and completed in 1927.

In addition, the District has done a certain amount of cleaning work along the river; has acquired sites and right of way; has investigated coal mine subsidence; has fought numerous legal battles; and has carried on a vast amount of administrative work. Under conditions found at Decatur, the completed sewage treatment plant has a capacity for a population equivalent of 150 000.

*The City and the Sanitary District of Decatur.*—The City of Decatur is on the Sangamon River about 50 miles by river above Springfield, Ill. The drainage area of the river above Decatur is about 862 sq. miles. The city has an area of 4 885 and the District of 21 120 acres. The trend of population is given by the following figures, the design having been based on an ultimate actual population of 120 000:

\* Transactions, Am. Soc. C. E., Vol. 91 (December, 1927), p. 441.

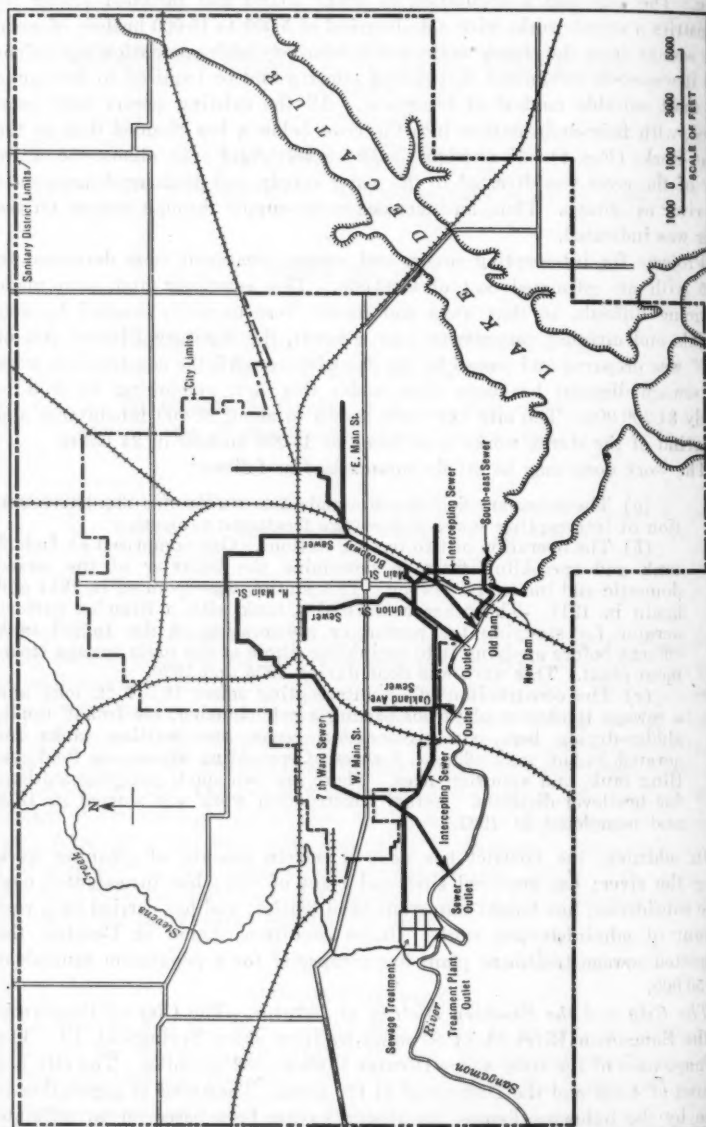

FIG. 1.—SANITARY SEWER LAYOUT, DECATUR, ILLINOIS.

Year.	Population.*	Year.	Population.*
1890.....	16 841	1930.....	57 500
1900.....	20 754	1940.....	71 000
1910.....	31 140	1950.....	84 000
1920.....	43 818	1960.....	99 000
1927.....	53 400		

The city is built mostly to the north of the river on ground 50 to 100 ft. above mean river level. This high ground is cut by several relatively deep watercourses extending northerly through the city, one or two of which have been drained and filled. The river valley is upward of  $\frac{1}{4}$  mile wide and, at present, the sewers reach the margin of the valley 20 ft. or more above mean river level. For the most part, ample drainage is available.

TABLE 1.—METEOROLOGICAL DATA.

Month.	Average temperature, in degrees Fahrenheit.	Prevailing winds.
January.....	26.5	NW.
February.....	27.3	NW.
March.....	40.9	SW.
April.....	52.0	SW.
May.....	63.3	SW.
June.....	72.0	SW.
July.....	76.3	SW.
August.....	74.6	SW.
September.....	67.8	SW.
October.....	55.8	SW.
November.....	42.2	NW.
December.....	30.3	NW.

The city has a large variety of industries, including a starch works, a structural steel company, railway shops, and many others. It is served by the Wabash, Illinois Central, Pennsylvania, Chicago and Indiana Western Railroads, and the Illinois Traction System.

*Meteorological Data.*—Decatur is located in the corn belt of Central Illinois. The average temperature and the prevailing winds are given in Table 1.

TABLE 2.—MEAN MONTHLY RAINFALL.

Month.	Rainfall, in inches.	Month.	Rainfall, in inches.
January.....	2.46	July.....	3.13
February.....	1.99	August.....	3.18
March.....	3.17	September.....	3.47
April.....	3.53	October.....	2.25
May.....	4.03	November.....	2.31
June.....	3.59	December.....	2.13

The weather retards construction work seriously during about three months of the year. Sludge drying on open beds can be done during about eight months. Sprinkling filters can be operated throughout the year, with reduced nitrates in the effluent through the winter months.

\* The population figures for 1890, 1900, 1910, and 1920, were taken from the United States Census reports; those from 1927 are estimated.

The mean annual rainfall is 35.05 in., with a mean monthly rainfall as shown in Table 2.

During wet seasons, the ground-water stands high and there is a marked infiltration into the sewers which increases the volume and lowers the temperature of the sewage. Unusually heavy rains occurred in the late summer and fall of 1926, as follows:

Month.	Rainfall, in inches.
July .....	2.23
August .....	7.47
September .....	16.56
October .....	6.18
November .....	3.09

*The Sangamon River.*—The Sangamon River, with a drainage area of 862 sq. miles above Decatur, flows through a relatively wide valley of cultivated bottom-lands and wooded areas which provide a large flood-water storage. Floods, therefore, are of relatively low intensity and long duration. There are United States and Illinois Geological Survey gauging stations on the river at Monticello, 27 miles above Decatur, and at Riverton, 42.5 miles below Decatur, both being approximate distances by river. The maximum flood of record was at the rate of about 25 cu. ft. per sec. per sq. mile. The mean monthly flow at Decatur, estimated from the gaugings, is as follows:

Month.	Mean monthly flow, in cubic feet per second.	Month.	Mean monthly flow, in cubic feet per second.
January .....	577	July .....	354
February .....	1 118	August .....	277
March .....	916	September .....	200
April .....	1 047	October .....	233
May .....	1 133	November .....	202
June .....	466	December .....	142

Two periods of very low flow occurred as listed in Table 3.

#### HISTORICAL STATEMENT

*Situation in 1913.*—The condition of the Sangamon River resulting from the domestic and industrial sewage of Decatur, became sufficiently offensive in the years prior to 1913, so that complaint was made and the assistance of the

Illinois State Water Survey was secured in order to compile a complete report. During 1912 and 1913, therefore, this organization made an extensive sanitary survey of the Sangamon River with special reference to pollution by the Decatur sewages. Its report included complete chemical and bacteriological analyses of the Sangamon River for a distance of about 20 miles below Decatur and recommended the installation of settling tanks and sprinkling filters.

*Rivers and Lakes Commission Order, 1914.*—Following the Water Survey report, further hearings were held by the Rivers and Lakes Commission and the Consulting Engineer for the City, Langdon Pearse, M. Am. Soc. C. E., made a report indicating the difficulties of the problem, due in part to the industrial sewage, and outlining the investigations necessary to a proper solution. As a result, the Commission ordered the pollution of the river to be removed by January 1, 1917, thereby allowing (as it thought) sufficient time for a thorough and careful study of the problem.

*Pearse and Greeley Report of 1915.*—On June 4, 1914, the City instructed Messrs. Pearse and Greeley, as Consulting Engineers, to undertake the necessary investigation, and their report was submitted on April 23, 1915. One of the major problems calling for special study was the effect on sewage treatment processes of the industrial sewages found in Decatur. Consequently, funds were appropriated for a testing station which was operated during the last half of 1914. The station was located near the mouth of the Broadway Sewer into which the wastes of the starch works, gas plant, and packing-house were discharged, in addition to the domestic sewage of 13 700 people. Unfortunately, the outbreak of the World War caused the starch works to shut down, so that tests were limited chiefly to the domestic sewage, as the other industrial wastes were very small in quantity. The station included a grit chamber, an Imhoff tank, a sprinkling filter, and a secondary settling tank. With a settling period of about 1.78 hours and the sprinkling filter dosed at an average net yield of 1 330 000 gal. per day per acre, 6 ft. 4 in. deep, the results of operation are shown in Table 4.

TABLE 4.—AVERAGE TESTING STATION RESULTS,

Suspended matter.....	34	23	32	.....

The report developed projects for intercepting sewers and sewage treatment works, recommending a high level sewer and a treatment plant comprising clarification works and sprinkling filters. It also included a careful discussion, with estimates of cost, of the activated sludge process in accordance with data then available.

*Test of Lime-Electrolytic Process, 1915.*—In 1915, the Electrolytic Sanitation Company made an offer to the City to build a small plant and to test its process in Decatur, with certain guaranties of its efficiency. The offer was accepted, the plant built, and on July 30, 1916, a 28-day test was begun. At the conclusion of the official test, the plant was given over for the City to operate.

The conclusions drawn by the City's representative may be summarized as follows: First, the process did not furnish a stable effluent except when excessive quantities of lime were used; second, the operating and upkeep costs were prohibitive; third, the method of sludge disposal was unsatisfactory; fourth, there was ample reason for differences of opinion as to whether the electrolytic action contributed materially to the efficiency of lime precipitation; and, fifth, the iron electrodes were subject to rapid corrosion—a new bank of electrodes was completely dissolved during two months' operation. On the basis of these findings, the electrolytic system was dismissed.\*

*Notes on Activated Sludge, 1916.*—In April, 1916, the Consulting Engineers worked up a project for an activated sludge plant located close to the outlet of the largest existing sewer. On the basis of securing power at 1.25 cents per kw-hr., the following total annual costs were shown:

1914 Report:

Sprinkling filters.....	\$58 572
Activated sludge, 2 cu. ft. air.....	90 188

1916 Notes:

Activated sludge, 2 cu. ft. air.....	\$63 360
--------------------------------------	----------

The lower cost in 1916 as compared with the 1914 estimates for activated sludge is partly due to a much reduced intercepting sewer cost and more favorable assumptions for excess sludge disposal.

At the request of the Decatur Association of Commerce, John W. Alvord, M. Am. Soc. C. E., was engaged to review the work done on sewage disposal and to report on the water supply. This report was submitted in May, 1917. It characterized the recommendation of the Consulting Engineers as "an obvious and conservative method of dealing with sewage"; and then suggested further investigation of two alternative projects—one comprising settling tanks and sand filters with a smaller intercepting sewer; and the other, settling tanks at each sewer outlet discharging into a so-called dilution pool formed by a low dam across the river.

From January to August, 1917, H. R. Lee, City Chemist, operated the testing station built in 1913. He reported to the City as follows:

(a) The Imhoff tank and sprinkling filter system will produce a stable effluent.

\* *Engineering Record*, November 11, 1916.

(b) The maximum rate at which a 90% stability could be maintained was found to be 1 000 000 gal. per acre per day. Whether this rate is sufficiently high to make the plan attractive from the standpoint of cost, and benefits derived, is a question for the engineer to decide.

(c) A rate of 1 250 000 gal. per acre per day could easily be secured were the Broadway sewage diluted with an equal volume of domestic sewage.

(d) The Imhoff tank will remove between 50 and 60% of the suspended solids. This is a good removal for a sewage of this type.

(e) The Worcester nozzle was found to give the better distribution of the two types used.

These tests were conducted on sewage from the Broadway Sewer made up of about 750 000 gal. per day of starch works sewage and about 1 500 000 gal. per day of domestic sewage, and having the following approximate analysis as taken into the testing station:

Item.	Parts per million.
Suspended matter.....	413
Total organic nitrogen.....	87
Oxygen consumed.....	200
Bio-chemical oxygen demand.....	700

In reviewing this report, it was found to be unsafe to estimate the rate of application of 1917 Broadway sewage, including the starch works sewage, at more than 800 000 gal. per day per acre. During the winter of 1916-17, a citizens' committee studied methods of financing the sewage disposal works and finally it drafted and secured the enactment of the Sanitary District Act which became effective in July, 1917.\* The first and only bond issue, amounting to \$860 000, was favorably voted, February 24, 1920. All other expenditures have been made out of annual taxes.

In November, 1917, a committee of the City Council reviewed the status of sewage disposal, visited about twelve sewage treatment plants in the East, and reached the following conclusions:

(a) From the processes observed at the sewage filter plants visited, the Commissioners felt that sand filters and contact beds were unsuitable to conditions at Decatur because of the large area required.

(b) That any process involving the use of lime as a precipitant would be unsuited to conditions because of the large quantity of lime required and the large volume of sludge which must be disposed of by some means.

(c) That Imhoff tanks and sprinkling filters would be suitable for the domestic sewage and if built of sufficient size would be suitable for the combined sewage and starch factory wastes.

(d) That activated sludge might be suitable for the disposal of Decatur sewage provided power could be obtained for less than 1 cent per kw-hr. and that some satisfactory method of dewatering, or disposing of, the sludge could be found.

The report then recommended the employment of consulting engineers and the preparation of plans and specifications.

*The Consulting Engineers' Report of 1918.*—This report was prepared shortly after the formation of the Sanitary District in 1917, to bring to date

\* Transactions, Am. Soc. C. E., Vol. 91 (December, 1927), p. 441.

in definite form all the various prior investigations. The conclusions of this report were briefly stated, as follows:

(a) The seriousness of river pollution at Decatur calls for remedial measures. Decided odors are produced, particularly adjacent to the city, but which continue in lessening degree 20 miles or more below the city.

(b) The project requires the construction of a high-level intercepting sewer to discharge at its lower end about 19 ft. above mean low water.

(c) The results of operation of the testing station (1917) indicate that the mixed domestic and industrial sewage can be treated on sprinkling filters. This type of treatment plant, therefore, can be considered reliable. The rate of treatment remains to be more closely fixed on a larger scale.

(d) Water storage is recommended as necessary for an additional water supply. Together with river regulation, it is a helpful factor which will materially improve conditions in the river during extremely dry weather.

The report also included an appendix on subsidence resulting from coal mining. As a result, the coal rights were purchased along nearly 3 500 ft. of right of way for \$7 500.

*Coal Mine Subsidence Report.*—In July, 1918, Professor L. E. Young, of the University of Illinois, submitted a report on ground subsidence under structures proposed by the Sanitary District, with recommendations, as follows:

(a) If possible, arrangements should be made to defer the construction of the Riverside Branch for a period of several years so that the coal under this section may be mined. Sewer construction should not begin at this point until three years after the coal directly beneath has been mined.

(b) On the basis of the reported market value of coal rights in this District it is recommended that a coal reservation be acquired along the line of the 1918 report. This should be a strip not less than 500 ft. wide.

(c) If the construction is to begin within three years, proper steps should be taken immediately to stop coal mining beneath those portions of the line which will be built.

*Notes on Starch Works Sewage, 1919.*—In the latter part of 1918, the owners of the starch works proposed to enlarge their plant for the manufacture of glucose, dextrine, and other corn products; and the City started preliminary studies for a large water-impounding project. Therefore, a review of the situation with special reference to the starch works sewage was made, and analyses of this sewage from various sources were summarized, as shown in Table 5. The report concluded that, based on a maximum grind of 25 000 bushels per 24 hours, not more than double the area of sprinkling filters would be required because of the starch works sewage, as compared with domestic sewage.

During the summer of 1919, some tests of the activated sludge process on starch works sewage at the plant were undertaken by the owners. The test was run for 77 days on gluten settler waste in a wooden tank 10 ft. in diameter and 10 ft. deep, holding 5 000 gal. A test of 4 days with straight waste gave no results. The sewage frothed over the tank and no sludge or nitrifying organisms were gained. The waste was then mixed with 4% of city sewage and later with an equal volume of city water with some better results. A test

was finally run with a mixture of the waste with two volumes of city water. This mixture had a temperature between 78 and 86° Fahr. The operation was established on the following basis:

	Time, in hours.
Filling .....	1.00
Aeration .....	19.00
Settling .....	3.0
Draining (dewatering).....	1.0

The quantity of air was not measured. The ratio of filter plate area to tank surface was 1 to 4.75, and the air was estimated at 2.3 cu. ft. per min. per sq. ft. of tank surface. Frothing ceased after 6 to 8 hours. The analytical results of a week's operation are given in Table 6.

*Survey of Industrial Sewage.*—From time to time since 1924, the engineers and the superintendent have investigated and reported on some of the minor industrial sewages. A small packing house, in a low-level area and with an average kill of 500 hogs and 70 cattle per week, was studied especially with reference to the operation of a small pumping station. The packing house was required to install a settling tank and grease basin on its sewer outlet. The chemical data obtained during these investigations are summarized in Table 7. All samples were 8-hour composites.

With the completion of the water-impounding project and the intercepting sewer, it became advisable to make a comprehensive general sewer plan for the entire city providing for new and relief sewers. The city was expanding and the newly built-up areas required sewerage. Many of the existing sewers were overloaded and needed relief. The City and District officials desired to have such sewers properly related to the sewage disposal and river improvement works. A general plan was prepared showing about six major sewer projects, with a total estimated cost of \$2 175 200. One of the projects, amounting to about \$360 000, was completed in 1927; and plans and specifications were ready for taking bids on another estimated to cost more than \$600 000.

As a result of all this effort, intercepting sewers and sewage treatment works have been completed and put into operation with an equivalent population capacity, under conditions at Decatur, of about 150 000. The owners of the starch works are completing process adjustments reducing the quantity and strength of its sewage to an approximate population equivalent of 1 000 per 1 000 bushels of grind. Construction work was first started in 1919, when the upper section of the intercepting sewer was let; and was completed in October, 1927, when the pre-aeration plant was put into operation.

#### DESIGN DATA

*Sources.*—The progressive design and construction of the Decatur sewage disposal projects over so many years, has made it possible to secure some design data from operating records, as, for instance, sewage quantities and characteristics at the treatment plant. In the first place (1914), weirs were built at the main sewer outlets and the rates of flow measured. As already noted, much design data came from the operation of the testing stations. The remainder was secured through the usual routine of local investigation.

*Population.*—The first population forecast and distribution of population over the city was made in 1915, and was reviewed in 1919 and 1925. The basis of design of works easily enlarged was 60 000, and of intercepting sewers and structures not easily enlarged, 120 000. An additional allowance was made for the sewage of major industries.

*Quantities of Sewage.*—The capacity of the intercepting sewer varies for different sections, as shown on Fig. 2. In the upper section where separate sewers are to be built, the capacity flowing full is for sewage at the rate of 1 000 gal. per capita per 24 hours from 20 000 people. This allowance includes capacity for a considerable industrial area. Then follows a short section taking combined sewage from about 250 acres located above the dam with a capacity of 5 750 gal. per capita per 24 hours from 28 700 population. There is an overflow just below the dam, and the capacity of the next section, which is largely in tunnel, is for sewage at the rate of 730 gal. per capita per 24 hours from 28 700 people. The next section, which is through a built-up part of the city, provides capacity for 950 gal. per capita per 24 hours from 68 000 people. The final section built largely in open country and, therefore, quite easily duplicated, has a capacity of 40 700 000 gal. per day equivalent to 340 gal. per capita from 120 000 people.

The first installation of sewage treatment works (Imhoff tanks, sprinkling filters, and appurtenances) was given a capacity for 60 000 people and 7 960 000 gal. per day, equivalent to 133 gal. per capita per 24 hours. This included 1 250 000 gal. per day of starch works sewage, equivalent to about 21 gal. per capita per 24 hours. When the additions to the sewage treatment plant were designed in 1926, the rates of flow (see Table 8) were estimated largely on the basis of meter records for about two years at the treatment plant.

Diameter (inches)	60	72	42	84	72	36
Capacity (M. G. D.)	40.7	84.6	21.0	165.0	93.5	20.0
Design Population	120 000	60 000	28 700	28 700		20 000
Per Capita	340	950	730	5 750		1 000

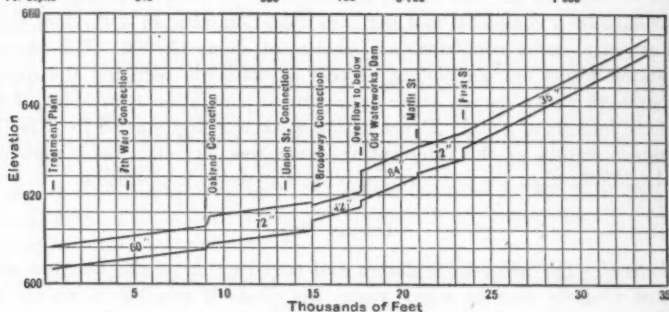

FIG. 2.—PROFILE OF INTERCEPTING SEWERS, DECATUR, ILL.

Including industrial sewage, the average dry season rate of flow is 167 gal. per capita per 24 hours from 60 000 people. It has been difficult to estimate the quantity of sewage from the starch works because of the rapid increase in the grind and the process adjustments resulting in changing quantities of sewage per bushel of grind.

Average.....	14.0	10.0
Maximum.....	16.0	....
Minimum.....	....	5.2

*Sewage Characteristics.*—A determination of the strength and character of Decatur sewage has been a most difficult element in the design. The domestic sewage is mixed with a variable industrial sewage from the starch works. This industrial sewage has increased with the grind from a population equivalent of 75 000 more or less during the period of 1914 to 1917, to one of more than 300 000 in 1926. In addition, the grind and the sewage vary with business conditions, the grind having recently ranged in a single

year from 20 000 to 45 000 bushels per day. The owners of the starch works, under the direction of Dr. Edward Bartow, have undertaken process adjustments to try and recover products which, until recently, were lost to the sewer, with a marked reduction in the strength of their sewage. The sewage first increased in strength with the growth at the starch works; and then decreased with the reduced waste.

#### CONSTRUCTION PROJECTS

*General.*—Construction work has proceeded almost continuously from 1919 to 1927 with a total expenditure chargeable to construction, including engineering, of \$1 666 783, and involving about fifteen general projects. Engineering supervision and inspection on these projects and during this time has equalled about 6.0% of the total amount of the final estimates.

The land for the sewage treatment plant is about 57 acres in area and cost \$7 419. Rights of way for the intercepting sewer cost \$11 702, of which \$7 500 was for the purchase of coal rights under the intercepting sewer. The total payment for right of way amounts to about \$1 per lin. ft. of sewer.

*Embankment for Intercepting Sewer.*—The first construction contract was for the embankment at the lower end of the intercepting sewer (1919). The embankment is about 2 900 ft. long and 12 ft. deep below the invert of the sewer at the point of maximum depth. It has a top width of 19.5 ft. for part of its length and 26.5 ft. for the remainder, with side slopes of 1 on 1.5. It was built of a somewhat sandy yellow clay put down in 12-in. layers and compacted by the travel of the teams. It was allowed to stand about 10 months before further use. After 5 years of service, there have been no signs of settlement. The sides have been planted with hay, clover, etc., and there has been no need of repairing them. The original contract comprised about 35 000 cu. yd. of embankment at \$0.34 per cu. yd. in place. All the material was taken from a borrow-pit near the right of way.

*Intercepting Sewers.*—The intercepting sewer built by the Sanitary District is 18 317 ft. long and cost \$598 000, or an average of \$32.60 per ft. In the three contracts under which it was built, alternate bids were taken on several types of construction and the least expensive type was selected with results, as follows:

Type.	Approximate length, in feet.
Monolithic concrete.....	5 700
Segmental block.....	8 700
Reinforced concrete pipe.....	3 600

*Sewage Treatment Works.*—The sewage treatment works were started in 1921 with the construction of the treatment plant by-pass. This was a 48-in. concrete sewer, 1 131 ft. long, including an overflow chamber, an outfall structure, and appurtenances. The sewer cost \$20.20 per ft.

Other construction projects at the sewage treatment plant were a roadway, 3 100 ft. long; an elevated tank with a capacity of 50 000 gal.; a ground-water supply; a sludge locomotive; and an electric power line. The total amount spent in connection with these various projects was \$653 143, including engi-

neering. Except for a rather liberal sludge capacity in the Imhoff tanks (3.03 cu. ft. per capita), the works so built have a capacity for a strong domestic sewage from about 60 000 people, indicating a cost of \$10.92 per capita.

In the spring of 1925, a small pre-aeration testing station was put into operation; and during 1926 and the first half of 1927, the sewage treatment plant was enlarged by the addition of pre-aeration tanks and appurtenances.

*South Main Street Pumping Station.*—A small low-level area of about 175 acres is served by the South Main Street Pumping Station. The area includes two small packing houses with an average kill of about 500 hogs and 70 cattle per week. The packing-house sewage passes through a small grease basin before reaching the pumping station. The pumping station contains bar screens with  $\frac{3}{8}$ -in. clear openings and two 4-in. vertical centrifugal pumps with motors operated by floats. The station is automatic in operation and is visited once a day for inspection, cleaning screens, and oiling. This station cost \$12 454 to build, and has an installed pump capacity of 1 000 000 gal. per day.

*Pre-Aeration Testing Station.*—During February and March, 1925, a small testing station (Fig. 3) was built to study the effect of partial or pre-aeration on sprinkling filter rates. The major items of construction are briefly described as follows:

(a) An aeration tank 12 ft. in diameter, 10.0 ft. liquid depth, and containing 6 570 gal. At 2 hours' displacement, this tank had a capacity for 78 000 gal. of sewage per 24 hours. It was fitted with a surface aerator or agitator of the Simplex type. The agitator wheel was 36 in. in diameter and operated by a 1-h.p. motor at 80 rev. per min.

(b) Originally, there were two settling tanks, each 5 ft. in diameter and 9 ft. liquid depth. At a sewage flow of 78 800 gal. per 24 hours the displacement period was 0.63 hours, with an area for about 2 000 gal. per sq. ft. per 24 hours, with both tanks in operation. These rates were found to be too high and a single tank, 10 ft. in diameter and 10 ft. liquid depth, was added. This provided a displacement period of 1.5 hours, with an area for about 670 gal. per sq. ft. per 24 hours, with all three tanks in service.

(c) The sludge re-aeration tank had a capacity of 810 gal. With 10% return sludge (8 000 gal. per 24 hours), the aeration period was about 2.5 hours.

(d) The sprinkling filter was 14 ft. in diameter and 6 ft. 4 in. deep, with one Taylor nozzle. It was filled with 1 to 2-in. stone from the large sprinkling filter; and dosed from a small tank controlled at first by a motor-driven butterfly valve, and, later, by an automatic siphon.

(e) In addition to the aeration tank, settling tanks, re-aeration tank, and sprinkling filter, the testing station included a blower, an air meter, a small pump to serve the sprinkling filter, a number of orifice boxes, and other appurtenances.

It took about a month to build the station and the costs were approximately as follows:

Materials .....	\$3 230
Labor .....	800
Engineering .....	652
Total.....	<hr/> \$4 682

*Covering Grit Chambers, Conduits, Gas Vents, Etc.*—The starch works sewage at Decatur contains very substantial quantities of sulfur dioxide and soluble organic matter which, with the domestic sewage, decomposes to form

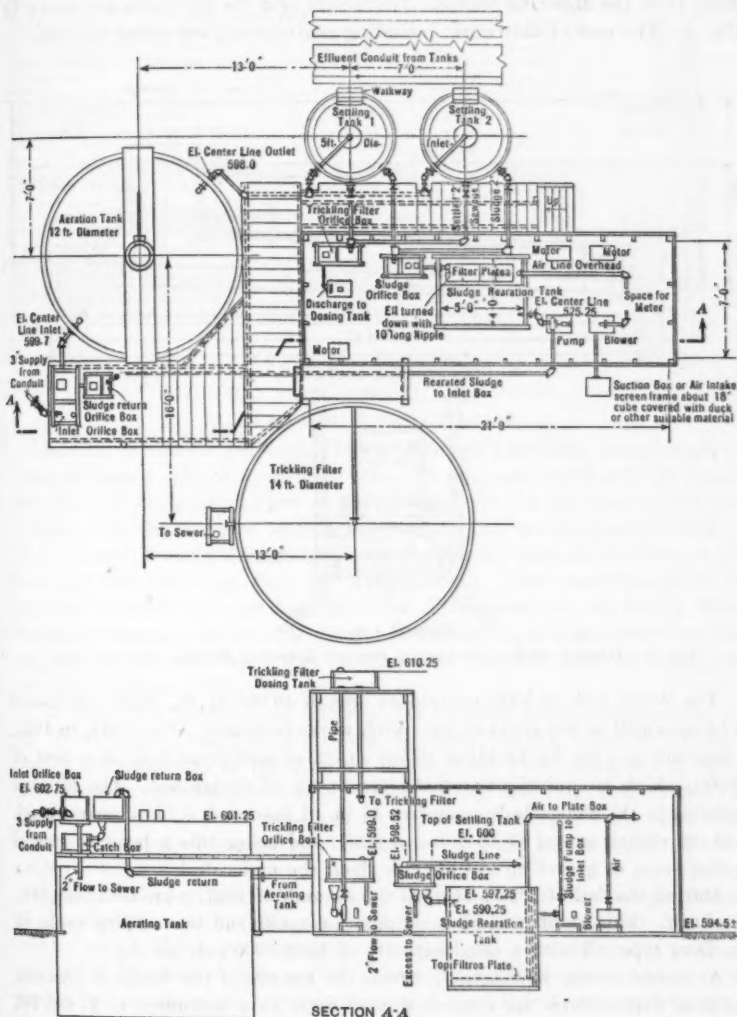

FIG. 3.—GENERAL PLAN, TESTING STATION, DECATUR, ILL.

hydrogen sulfide. This decomposition is greatly accelerated by the relatively high temperature. To reduce such odors, concrete covers were built during the summer of 1926 over the grit chamber and the conduits and gas vents of

the Imhoff tanks. The spaces under the covers of the grit chamber and conduits were connected by pipes to a suction fan which delivered the confined air and gases to a small brick furnace in which they were burned with the gases from the digesting sludge. The covers over the gas vents are shown in Fig. 4. The cost of this work, including engineering, was about \$15 000.

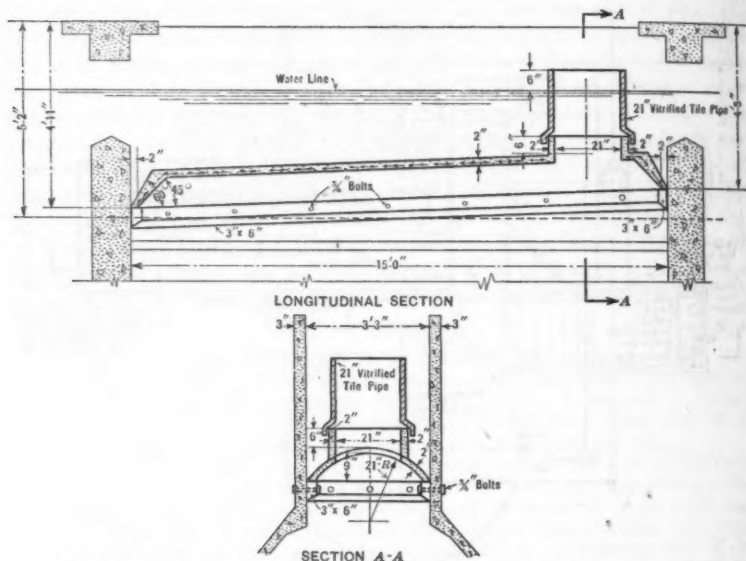

FIG. 4.—DETAILS OF GAS COLLECTOR, SEWAGE DISPOSAL WORKS, DECATUR, ILL.

The sludge beds as built covered an area of 40 000 sq. ft., which was found to be too small as the grind at the starch works increased. Therefore, in 1926, a contract was let for building 16 500 sq. ft. of additional beds at a cost of \$9 000, which is equivalent to \$0.55 per sq. ft. of sludge bed. The filtering material in the sludge beds comprises 1½ in. of fine sand, 3 in. of coarse sand, 4 in. of roofing gravel (¼ to ¾ in. in size), and below this a layer of graded broken stone or gravel up to 2-in. size about the under-drains.

During the fall of 1926 and until the autumn of 1927, a pre-aeration plant was built. This plant comprises six aeration tanks and two settling tanks of the Dorr type, all with a rated capacity of 10 000 000 gal. per day.

As nearly as may be determined from the records of the Sanitary District, the total expenditures for construction projects have amounted to \$1 666 783 (see Table 9). Active construction work started just after the World War in 1919 and was completed in 1927, covering nine construction seasons. This is a total cost of \$33.30 per capita, based on 50 000 population for the period of construction.

## WATER-IMPOUNDING PROJECT

*Relation to Sewage Disposal.*—The need for an additional water supply for Decatur became evident as early as 1914. The unregulated flow in the Sangamon River is frequently as low as 5 000 000 gal. per day for several months at a time. On one occasion only the fortunate and unexplained blowing up of a channel dam up stream let down a sufficient volume of water to tide over the situation. By 1920, the average daily water consumption of the city was 5 540 000 gal. per day, exclusive of the needs of the Staley Manufacturing Company for cooling water. Consequently, a large water-impounding project was undertaken and an earth and concrete dam put under construction in June, 1920.

At that time the Sanitary District was building intercepting sewers, and the Trustees were asked to contribute Sanitary District funds in consideration of the possibility of the diluting and flushing water as an aid to sewage disposal during periods of low flow. Computations, however, demonstrated that there would not be a sufficient quantity of water available from the storage reservoir to supply enough oxygen for the sewage, and no appropriations were made for this purpose.

Taking 500 parts per million as the approximate average oxygen demand of the sewage, a sewage flow at the rate of 10 000 000 gal. per day would require about 42 000 lb. of oxygen per 24 hours. Assuming 5.0 parts per million of dissolved oxygen available from the reservoir water and no measurable flow in the river, it would require a discharge from the reservoir at the rate of 1 000 000 000 gal. per day. Obviously, nothing like this rate of discharge was possible except for very short periods, as the safe yield of the impounding project was estimated at about 35 000 000 gal. per day. Nevertheless, the river near the city has been freshened by the occasional discharge of reservoir water as indicated in Table 10.

*Brief Description.*—Lake Decatur is formed by an earth and concrete dam across the valley of the Sangamon River. The total length of the dam is 1715 ft. At the north end is an earth embankment, 510 ft. long. The center section, a solid concrete spillway, 525 ft. long, is 28.5 ft. high and has a width at the base of 72 ft., including the down-stream concrete apron. There is an up-stream clay apron, 28 ft. wide, making the total width of the base of the dam 100 ft. A movable crest is built on top of the spillway by which the water level can be raised 2.5 ft. up to Elevation 612.5.

Extending under 1 500 ft. of the length of the dam is a line of sheet-piling largely of steel, but with wood sheeting at either end. Under the concrete part of the dam (see Fig. 5), the steel sheet-piling extends down about 30 ft. to a firm connection with a layer of hardpan glacial till. At the north end of the spillway, a gate chamber has been provided so that 1 000-h.p. water turbines can be installed if desired.

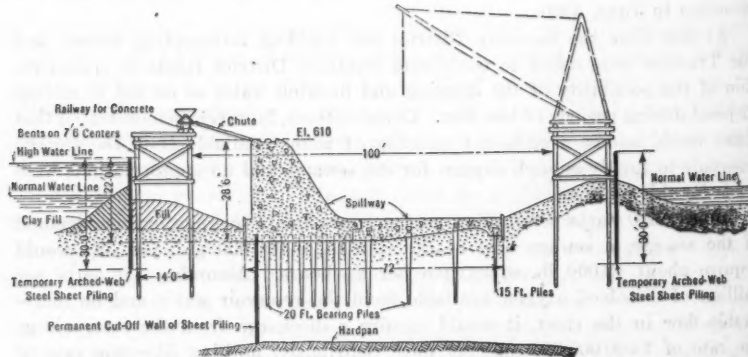

FIG. 5.—CROSS-SECTION OF COFFER-DAM FOR CONCRETE SPILLWAY OF DAM, DECATUR, ILL.

The dam was built on a sandy gravelly formation underlying the valley soil and overlying the Wisconsin and Illinoisan tills. The Wisconsin till

(or drift) is of terminal moraine origin and the Illinoian of ground moraine structure. Thus, the Illinoian till is very hard and dense with a maximum content of impervious clay. For the most part the steel sheeting was driven into this formation effecting a very good cut-off.

The reservoir back of the dam covers about 3 000 acres and extends up stream about 12 miles, with an average width of somewhat less than  $\frac{1}{2}$  mile. The volume of the reservoir is from 6 000 000 000 to 8 000 000 000 gal. and the average depth 7.5 ft. About one-fourth of the area was timbered and had to be cleared. Nearly fifty buildings were removed and 17 miles of marginal and cross-highways were raised, relocated, and protected with paving.

*Method of Financing.*—The water-impounding project cost more than \$2 000 000. The City had available the proceeds of two bond issues amounting to somewhat more than \$600 000. Money from annual taxes was appropriated for construction purposes, amounting to more than \$250 000. It was necessary, therefore, to raise about \$1 300 000 in some other way. The plan adopted was to form a local water company of Decatur citizens that was to issue stock and notes secured by the reservoir land and by a contract with the City to pay the water company enough to provide a 7% rate of interest and to retire the stock in 16 years. This stock in the amount of \$1 000 000 was over-subscribed in a short campaign, and the necessary funds were secured. By other subscriptions and loans this amount was raised to more than \$1 300 000.

The cost of the water-impounding project may be summarized, approximately, as follows:

Item.	Amount.
Land for dam.....	\$30 000
Dam .....	815 000
Reservoir land.....	610 000
Clearing .....	115 000
Roads and bridges.....	400 000
Road embankment protection.....	200 000
Engineering for dam.....	40 000
Surveys and miscellaneous.....	50 000

Total .....	\$2 260 000
-------------	-------------

The dam was built under a cost-plus contract, with a participation clause and an upper limit of \$1 025 000. The unit costs of the major items were stated in the contract, as follows:

Item.	Amount.
Stripping .....	\$1.10 per cu. yd.
Earth excavation above Elevation 595.0	0.52 " " "
Earth excavation below Elevation 595.0	0.92 " " "
Earth borrow.....	0.52 " " "
Rock excavation.....	3.00 " " "
Earth embankment, Class A.....	0.17 " " "
Earth embankment, Class B.....	2.30 " " "

Item.	Amount.
Placing loam.....	\$1.70 per cu. yd.
Seeding .....	0.06 " sq. yd.
Drainage for slope paving.....	0.23 " lin. ft.
Slope paving.....	1.55 " sq. yd.
Steel sheet-piling, Class A.....	0.07 " lb.
Steel sheet-piling, Class B.....	0.06 " "
Wooden sheet-piling.....	1.05 " sq. ft.
Concrete in spillway.....	12.20 " cu. yd.
Concrete in gate setting .....	17.00 " " "
Concrete in apron .....	9.20 " " "
Concrete in toe-wall.....	15.00 " " "
Concrete in abutments .....	13.70 " " "
Concrete in conduit .....	25.00 " " "
Reinforcing steel .....	0.06 " lb.

## NOTES ON STARCH WORKS

*Growth of Starch Works.*—In 1912, the cornstarch factory began operating. The capacity of the plant at that time was about 10 000 bushels of corn per 24 hours which, by 1915, had increased to 15 000 bushels. Then, due to the World War, the plant was practically closed until 1917, when regular operation was resumed. Since that time it has operated almost continuously with a progressively increasing grind to as much as 45 000 bushels per 24 hours. The products of manufacture have lately been diversified, so that at present various types of cornstarch, gluten meal, dextrine, glucose, corn sugar, corn oil, soy bean oil, and soy bean meal are produced. The Company employs about 2 000 hands when operating near the rated capacity.

The rather phenomenal growth was entirely unanticipated, even by the officials of the industry itself. In 1918 when plans for the Decatur sewage treatment plant were being formulated, the grind was less than 15 000 bushels of corn per 24 hours. The Company fully stated its plans for the future, which anticipated a maximum daily grind of 25 000 bushels and the erection of a plant for converting wet starch into glucose and corn sugar. The glucose plant was built to take advantage of the market prices of dry starch and glucose so as to secure the best gross revenue. This plant did not in itself increase the corn-grinding capacity of the starch plant, nor was it anticipated that it would. In reality, however, it has been the cause of doubling the anticipated corn grind, through better adjustment to the market and a consequent growth of business.

*Plant Processes and Wastes.*—Briefly, the process of manufacture is as follows: (a) Steeping the corn in a dilute sulfur dioxide solution for a number of hours; (b) crushing the steeped corn and separating the germ from the hull; (c) grinding the hull, and separating the husks from the ground meal; (d) separating the starch and gluten by sedimentation and flotation; (e) washing and drying the starch and gluten; and (f) converting wet starch to glucose and sugar.

A certain amount of liquid waste results from each operation. In some cases the wastes are re-used in the plant for carrying purposes and thus return

sewage treatment plant was predicated, with the expectation that the condenser water would be by-passed direct to the river if desired.

The sewage treatment plant was placed in operation in May, 1924, and during its initial running the total quantity of mixed sewage was between 15 000 000 and 17 000 000 gal. per 24 hours. This comprised about 5 000 000 gal. per day of domestic sewage from the city and from 10 000 000 to 12 000 000 gal. per day of industrial sewage from the starch works. Investigation showed (a) that the starch works were grinding about 35 000 instead of the anticipated 25 000 bushels of corn per day; (b) that the Company's sewers were arranged so that the 6 000 000 to 10 000 000 gal. of condenser water could not be separated from the strong sewage for diversion into the river; and (c) that the private 24-in. sewer, through which the condenser water was to have been diverted, was of insufficient capacity.

Investigations and analyses of the glucose condenser water showed that it was practically of the same character as the raw water before entering the condenser, except for occasional entrainments of glucose or sugar. By careful operation of the evaporation pans it was thought that this entrainment could be reduced to a negligible minimum. The Company, therefore, was allowed to construct a conduit for returning this condenser water to the impounding reservoir. This was completed and placed in operation in July, 1925, and relieved the sewage treatment plant of from 6 000 000 to 10 000 000 gal. per day of relatively hot condenser water, the volume depending on the season of the year and the temperature of the cooling water from the lake. This diversion reduced the volume of sewage received at the treatment plant to about 11 000 000 gal. per day, 50% of which was from the starch works and the remaining 50% from the city.

*Characteristics of Mixed Sewage.*—The five-day bio-chemical oxygen demand of the week-day city sewage, when the starch works is not in operation, is about 125 parts per million. The average monthly bio-chemical oxygen demand of the mixed sewage, including that from the starch works, varies directly with the corn grind and inversely with the volume of sewage, and has ranged from 500 to 800 parts per million in dry weather.

The temperature of the mixed sewage as received at the treatment plant has varied from 70 to 104° Fahr. during winter and summer, respectively. These very warm temperatures caused rapid decomposition of the mixed sewage, so that when it reached the sewage plant, hydrogen sulfide odors resulted. These odors were intensified after the condenser water was removed from the sewers, due to the greater concentration of the mixed sewage so that paint on houses a mile from the plant was discolored.

*Population Equivalent and Its Reduction.*—Analyses of the city sewage and the starch works sewage at this time indicated a total population equivalent of about 350 000 for the mixed sewage as received at the treatment plant, of which about 300 000 was contributed by the starch works. These figures were obtained by dividing the total pounds per 24 hours of 5-day bio-chemical oxygen demand by 0.17 lb. as the per capita contribution of

5-day bio-chemical oxygen demand.\* This factor seems to apply satisfactorily to the Decatur domestic sewage population equivalent when the starch works is shut down. The estimated human population connected to the sewers is about 40 000 and the minor industrial population equivalent, exclusive of the starch waste, is between 10 000 and 15 000. (See "Survey of Industrial Sewage," page 554.)

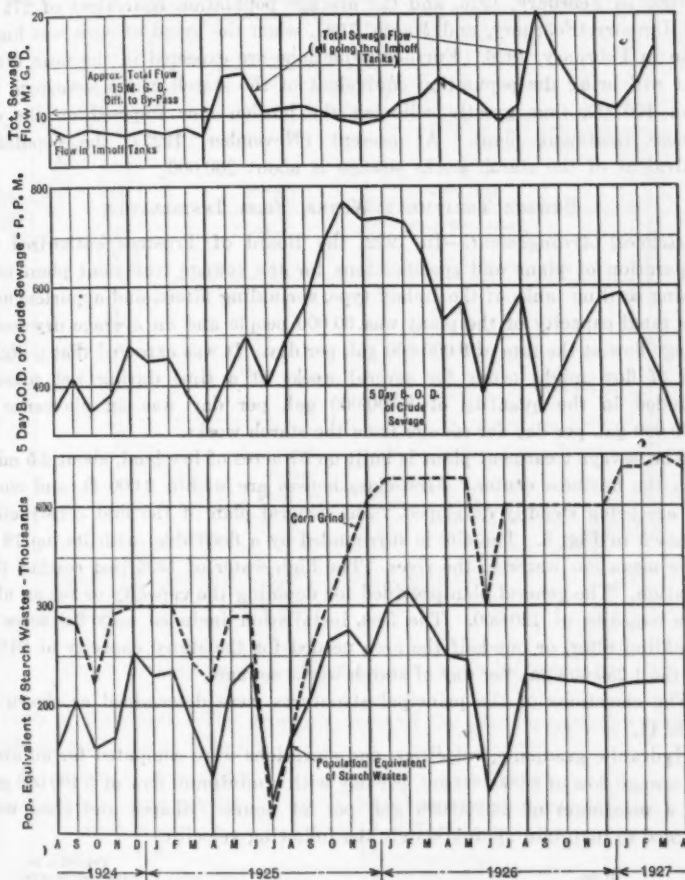

FIG. 7.—STARCH WORKS DATA.

On Fig. 7 is shown the quantities of sewage, in million gallons per day, the 5-day bio-chemical oxygen demand, in parts per million, the corn grind, in bushels per 24 hours, and the population equivalent of the starch works

\* Calculated from average of eight cities, U. S. Public Health Service Bulletin 132, pp. 35-111.

sewage for 1924-27. The population equivalent of the starch works sewage was calculated by subtracting 50 000 from the total population equivalent as determined from the regular daily analyses of composite samples of the mixed sewage received at the sewage treatment plant.

These curves show that the Company has improved its operation and decreased its losses as indicated by the maximum population equivalent of 370 000 in February, 1926, and the average population equivalent of 275 000 for January, February, and March, 1927, when the grind of corn was higher than in February, 1926. Further reductions are expected in the near future that will bring the population equivalent of the starch works sewage to less than 100 000, thus greatly relieving the burden now imposed on the city sewage treatment plant. At present (November, 1927), the population equivalent of the starch works sewage is about 260 000.

#### SEWAGE TREATMENT WORKS, FIRST INSTALLATION

*General Arrangement.*—In 1922, the Board of Trustees authorized the preparation of plans and specifications for the sewage treatment plant comprising settling tanks of the Imhoff type, sprinkling filters, and appurtenances. The rated capacity of the plant was 60 000 people and an average dry-season sewage flow at the rate of 8 000 000 gal. per day. It was expected that a higher rate of flow might occur for several weeks at a time during wet seasons. Included in the quantity of 8 000 000 gal. per day was an allowance of 1 250 000 gal. per day for sewage from the starch works.

The sewage treatment plant is built on 57 acres of low land, about 2.5 miles from the business center. First-class houses are within 2 000 ft. and closer lots are being steadily developed. The general plan of the first construction is shown in Fig. 8. The site is surrounded by a flood dike with its top 19 ft. above mean low water in the river. The high water of 1926 just reached this elevation. The general plan provided for doubling the capacity or for an ultimate capacity of 120 000. The first installation included only 3.0 acres of sprinkling filter, or one-half the area needed for the stated capacity of 60 000 and the 1 250 000 gal. per day of starch works sewage.

The elevations of the principal structures were determined as shown in Table 11.

Hydraulic gradients, velocities, and elevations were computed for an average sewage flow of 8 000 000 gal. per day with a minimum flow of 5 400 000 gal. and a maximum of 44 200 000 gal. per 24 hours. Shapes and sizes were designed to maintain approximately the following velocities:

Item.	Velocity, in feet per second.
Grit chamber .....	1.0
Conduit to settling tanks.....	1.0
Settling tank influent conduits.....	1.0
Settling tank effluent conduits.....	0.5
Sprinkling filter collecting conduits.....	1.5
Main effluent conduits.....	2.0

The total loss of head is thus 20.91 ft., of which 1 ft. was included ahead of the settling tanks as a contingent allowance to permit installation of sewage treatment devices not developed at the time of design.

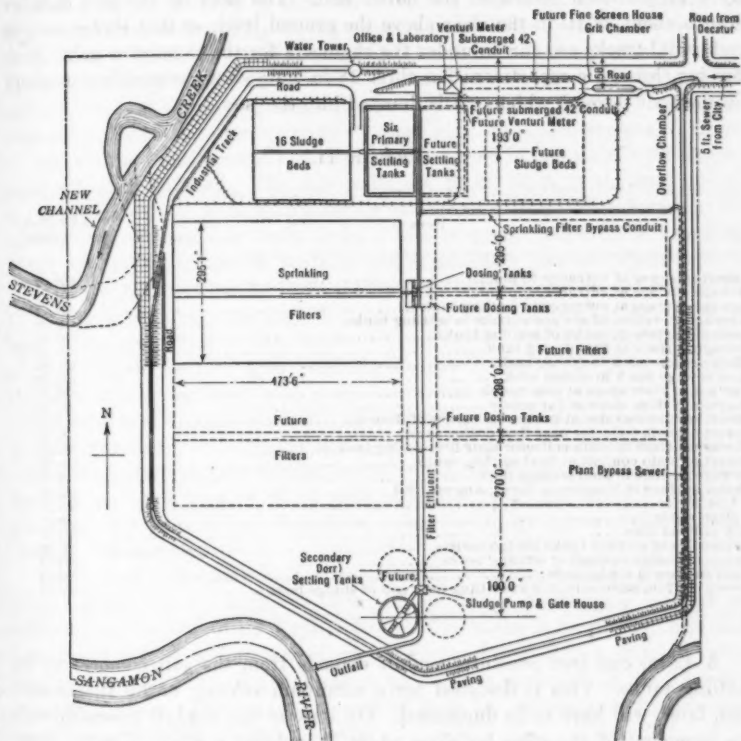

FIG. 8.—GENERAL PLAN, SEWAGE TREATMENT PLANT, DECATUR, ILL.

*Parts of the Plant.*—The principal parts of the plant comprising twenty-one items, are listed as follows:

- |                             |                                     |
|-----------------------------|-------------------------------------|
| 1.—Plant by-pass sewer.     | 12.—Filter by-pass.                 |
| 2.—Connecting sewers.       | 13.—Final settling tank by-pass.    |
| 3.—Coarse screen.           | 14.—Water supply.                   |
| 4.—Grit chamber.            | 15.—Lighting.                       |
| 5.—Venturi meter and house. | 16.—Industrial railway.             |
| 6.—Imhoff tanks.            | 17.—Drainage system.                |
| 7.—Sludge beds.             | 18.—Office building and laboratory. |
| 8.—Dosing tanks.            | 19.—Flood protection.               |
| 9.—Sprinkling filters.      | 20.—Planting.                       |
| 10.—Final settling tanks.   | 21.—Roadways.                       |
| 11.—Outlet to river.        |                                     |

The grit chamber\* comprises three flowing-through conduits, each 75 ft. long. Two of these conduits are 8.0 ft., and the other, 10.0 ft., wide, with 1½-in. clear openings. The velocity and depth of flow in the conduits are maintained by a proportional orifice at the outlet end. The floor of the grit chamber stands about 8½ ft. in the clear above the ground level, so that sludge cars on industrial tracks are run in under the chambers for the remaining grit. Each flowing-through compartment has three 18-in. gate-valves controlling openings in the floor through which grit is dumped into the cars.

A 42-in. cast-iron pressure conduit extends from the grit chamber to the settling tanks. This is designed for a minimum velocity of 1.0 ft. per sec.; and, later, will have to be duplicated. On its way the conduit passes through the basement of the office building where it includes a 42-in. Venturi meter tube, the register and recorder of which are set in the office above.

The settling tanks are of the two-story or Imhoff type. The first installation comprises six units, each 27 ft. 10 in. wide and 96 ft. long, inside the walls at the top. The liquid depth is 27.0 ft. and the free-board is 24 in. In each tank are two flowing-through or settling compartments. There are three gas vents in each of the three tanks having a total width of 9.0 ft. equivalent to 31.1% of the total tank surface.

The six settling tanks provide the following capacities:

Item.	Cubic feet.
Settling .....	63 700
Sludge .....	181 900
Neutral zone } .....	83 000
Scum } .....	

\* Transactions, Am. Soc. C. E., Vol. 91 (December, 1927), p. 535.

These volumes provide a displacement period of 1.44 hours in the settling compartments when the flow is 8 000 000 gal. per day, and 3.03 cu. ft. per capita in the sludge compartment.

There are two conduits at each end of the settling tanks and a single conduit along the outside of each of the two end tanks, which provide for reversal of the flow. The sewage flow is controlled by so-called "cone orifice" valves. These have proved to be very satisfactory in operation with relatively uniform and complete use of the displacement capacities of the six tanks. The sewage flows out of each tank over weirs 16 ft. long, with suspended screens in front.

The settling tanks are built of reinforced concrete in two units with a main expansion joint between. The side walls are 20 in. thick at the bottom and are tied together by cross-walls heavily reinforced. The baffles forming the settling compartment were built up by a cement gun shooting on to expanded metal, with resulting smooth surfaces and satisfactory results. Each baffle is divided into three sections by vertical expansion joints over each end cross-wall.

Sludge is withdrawn through 8-in. cast-iron sludge pipes having 4.5 ft. of head on the center line of the outlets. These outlets are controlled by sluice-gates and discharge into open conduits leading to the sludge beds. Each of the tanks is fully equipped with a pressure water system.

The first construction work included 40 000 sq. ft. of sludge bed area with provision for an extension (since made) of 16 500 sq. ft. There were originally sixteen sludge beds equally divided on the two sides of a central sludge conduit. Each bed is 100 ft. long by 25 ft. wide, separated from the others by concrete plank partition 2 in. thick. Industrial track for sludge cars are placed along the center of each bed.

Two dosing tanks form part of the operating unit of 3 acres of sprinkling filters. Each tank contains one 30-in. Miller siphon discharging through an independent pipe line to 1.5 acres of filters. The tanks as originally built each held 15 500 gal. of sewage and discharged once every 7 to 9 min. Sloping bottoms were built into the tanks after tests of the operation of the filter distribution system. The maximum rate of flow for maintaining intermittent operation is 7 440 000 gal. per 24 hours.

The sprinkling filters are built in units of 1.5 acres, each 473.5 ft. long and 140.5 ft. wide, with one unit on each side of a common pipe gallery. The depth of filter stone over the under-drains varies from 5.67 to 6.33 ft. The surface of each filter slopes away from the dosing tanks 0.8 ft. in 470. The under-drains are of the trough type covered with vitrified clay blocks and slope to a main collector in the pipe gallery at the rate of 0.67 ft. in 145. Except for a thin layer of larger stones over the under-drains, the filter stone is 1 to 2 in. in size. Each filter unit has 430 round-spray sprinkler nozzles of the Taylor type. The lateral distributors of 6 and 8-in. pipe are spaced 11.5 ft. on centers and the nozzles are 13.25 ft. apart on each lateral. The filter floor is of unreinforced concrete 5 in. thick, built in strips 10 ft. wide.

The effluent from the sprinkling filters flows through a main outfall conduit to the final settling tank. The first construction included only one final settling tank out of four proposed for the ultimate capacity. This tank

is circular and has a liquid depth of 11.19 ft. at the center. The sewage is discharged at the center, 9.11 ft. above the bottom of the tank, and flows radially to weirs at the circumference. The sludge is removed by a Dorr mechanism to sludge pumps of the Barnes type set in an adjacent building. These pumps have a suction lift of about 11 ft., a capacity of 59 gal. per min., and operate satisfactorily. The settling tank is built of reinforced concrete with a bottom 48 in. thick to compensate upward pressure.

At a sewage flow of 8 000 000 gal. per day, the rating of the final settling tank is 1810 gal. per sq. ft. of tank surface per 24 hours, or a displacement period of 37 min. Sludge is pumped through a wood stave force main over the dike to bottom-land along the river.

The office and laboratory building is about 30 ft. square and contains two floors and a basement. The upper floor is intended for living quarters for workmen, but has never been furnished for use. The basement contains the heating plant, a shop, and space for the sludge locomotive. The intermediate floor is partitioned into four rooms, two of which are fully equipped laboratories, one is the office, and the fourth, a drafting-room. The space appears to be ample. The building is of common brick with asphalt shingles.

The water supply for the plant comes from an infiltration gallery approximately 6 ft. in diameter and delivering by gravity through a 4-in. supply main about 300 ft. long to a centrifugal pump in the basement of the office building. The water is pumped into an elevated tank of 50 000 gal. capacity and is distributed about the grounds.

Trains of six sludge cars are hauled by a Plymouth gasoline locomotive to a sludge dump along the west dike. Some sludge has been pumped wet to adjacent cornfields.

The grounds about the plant are under-drained, but very little landscaping has been undertaken as yet. There is a by-pass sewer for the entire plant and one for the sprinkling filters.

#### OPERATION OF SEWAGE TREATMENT WORKS, 1924-1927

*Quality of Sewage.*—The quantities and characteristics of Decatur sewage are shown in Table 12 which gives the average monthly data. The chemical data are determined according to the Standard Methods of Water Analysis (American Public Health Association, 1923) on daily samples composited hourly and kept at 10 to 20° cent. in a water bath. The data are discussed under three divisions, A, B, and C, as follows:

Division A is the data from August, 1924, through June, 1925. During this period 6 000 000 to 8 000 000 gal. of relatively pure condenser water from the glucose refinery were discharging into the City sewers, thereby increasing the total dry-weather volume of sewage to 15 000 000 gal. per day, or more. Of this quantity, 6 500 000 gal. per day was by-passed around the plant, 8 500 000 gal. per day was passed through the Imhoff tanks, and all but 3 000 000 to 4 000 000 gal. per day was again by-passed around the filters. The data show the sewage of this period to be one of normal suspended matter, high in total nitrogen, oxygen consumed, and bio-chemical oxygen demand, but only one-half as strong as that received during the period discussed under Division B.

Division B is the data from July, 1925, through August, 1926. During this period the refinery condenser water was not entering the sewers, but was being returned to the impounding reservoir. This period was characterized by a normal rainfall and a steady increase in the corn grind from month to month. However, the efficiency of operation of the starch plant was improved after November, 1925, so that the strength of the sewage at higher corn grinds was less than it had previously been at a much lower grind.

\* Calculated total sewage, including by-pass.

Division C is the data for eight months of abnormally high rainfall and river stage, with dilution of the sewage by storm water and infiltration. This period also represents further increases in efficiency at the starch works, as indicated by the decrease in population equivalent. The general trend of the chemical quantities was downward, due partly to dilution by infiltration and storm water, and partly to greater efficiencies at the starch works.

*Operating Details.*—The sewage passes first through a bar screen with openings between the bars of 1½ in. From June 1, 1924, to September 1, 1926, a total of 110 cu. yd. of screenings was removed. This represents 0.0153 cu. yd., or 0.4 cu. ft., of screenings per million gallons of sewage. The screenings are buried daily.

The grit chambers are operated alternately and the velocity of flow is entirely controlled by the orifice weir at the outlet. The character of grit usually obtained is mostly sand, cinders, and fine coal. At certain periods of the year there is a tendency for paunch manure from two packing houses to settle toward the outlet ends of the chambers. This material is obnoxious to handle, but dries rapidly and causes no odor where used as fill.

The total of 541.5 cu. yd. of grit, or 2.16 cu. ft. per million gallons of sewage, has been obtained in 24 months of operation. The grit has been used for filling in low places and for replacing sand in the sludge drying beds. It has not been entirely satisfactory for this latter purpose because of its low density, which allows it to adhere to the dry sludge and be removed too rapidly from the beds. The possibility of using a sand-washing machine for reclaiming the heavier sand from the drying beds is being considered.

The Imhoff tanks have operated most satisfactorily considering that they have been run most of the time at 35% above their designed capacity. The resulting larger volume, due to the increased industrial sewage and the lack of sludge bed capacity, has caused the sludge to reach the slots of the flowing-through compartments each winter in January, thus reducing the efficiency of the tanks during January, February, and March. Fig. 9 shows the sewage flow and the percentage-removal of suspended matter in the Imhoff tanks to date (1927). The removal of bio-chemical oxygen demand has been between 20 and 22 per cent. This low result is attained because of the large amount of colloidal material in the starch works sewage.

Sewage was started through the Imhoff tanks on May 15, 1924, and vigorous foaming began on July 24, 1924. The foam rose over the free-boards of the gas vents and covered the flowing-through compartment to a depth of about 1 ft. However, well-designed scum-boards held the foam back so that very little of it escaped in the effluent of the tanks. Stirring and hosing the tanks added to the troubles at least temporarily. After about six weeks, the foaming stopped and was not again experienced until after the three-month shut-down in the summer of 1926 for the installation of the gas collectors. During the shut-down the sludge remaining in the tanks practically stopped gassing and apparently did not properly seed the fresh sludge when the tanks were again started in July. Numerous laboratory tests have shown that old sludge may become dead, so to speak, in so far as its inoculating capacity is concerned. Beginning in the fall of 1926, some of the tanks foamed mildly for three months, but in December the foaming became so violent that many of the gas-collecting domes were disconnected to prevent foam from entering the gas-piping system. It became necessary to remove the wooden sludge screen in each gas collector, because the "sludge-scum" which accompanied the foaming was very slimy and clogged the openings in the screen, thus creating considerable pressure. On releasing the screens some were blown from 4 to 6 ft. into the air, and the workmen got a foam shower bath.

Analyses of the gas during foaming show a high carbon dioxide content. The pH of the sludge liquor, at this time, was about 6.4, thus indicating that

the acidity needed correction. To obtain some practical information on these foaming troubles several experiments were made.

One tank was not treated in any way; that is, foaming was allowed to take its own course. This tank foamed continuously for two months.

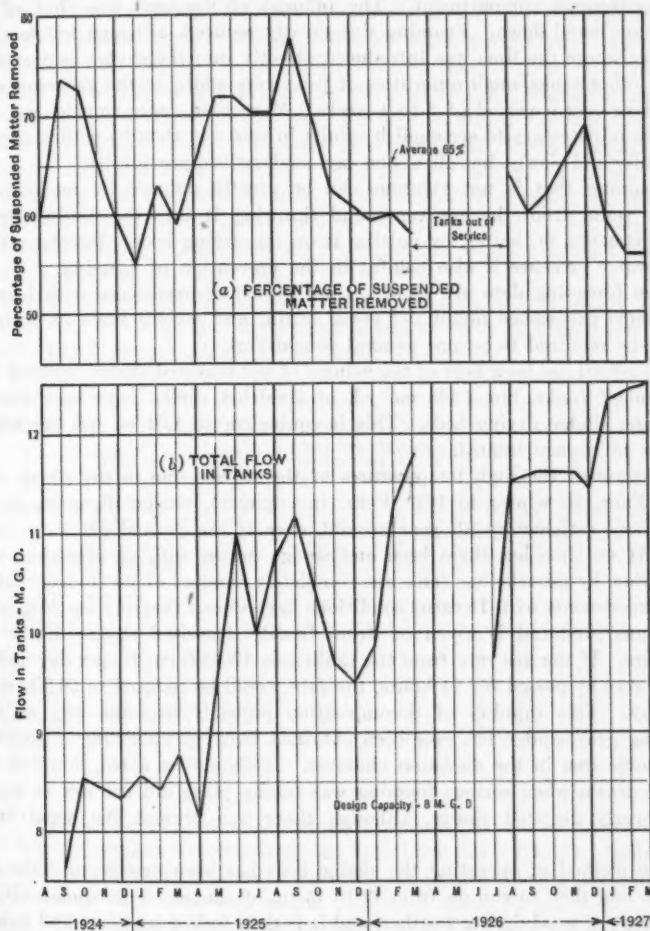

FIG. 9.—RESULTS OF OPERATION OF IMHOFF TANKS.

In one tank the depth of sludge liquor was measured from the surface to the solid sludge layer in the bottom. The acidity of the sludge liquor was titrated with Brom-thymol blue to a pH of 7.0, and the necessary quantity of lime calculated. The lime was added to each hopper down the gas-collector chimneys, through a chute, with a stream of water. This chute delivered the

lime-water mixture about 4 ft. below the surface of the scum. Within 24 hours foaming had stopped, and the gas-collecting system was reconnected and placed in operation.

In another tank the lime was placed on top of the "foam-scum" in the flowing-through compartment. The influent of the tank was shut off and the scum hosed down. Foaming was greatly reduced, although not so effectively as where the lime was introduced directly into the sludge compartment.

In other tanks small quantities of lime were added to the gas vents every few days over a period of 2 to 4 weeks. More lime, more trouble, and more time were necessary to accomplish results in this way than by adding the lime carefully and slowly, but all in one day, as described previously.

Foaming that is not vigorous can be greatly reduced by removing the sludge scum from the gas vents and throwing it into the flowing-through compartments, or, better, by putting it on the drying beds. Regular stirring with water pressure is also helpful in the prevention of foaming.

The foregoing data are based on one period of experience with foaming. The same experience might not occur again, and several years of operation would be required to permit general conclusions.

No record has been kept of the volume of wet digested sludge removed from the Imhoff tanks, but 7 493 cu. yd. of air-dried sludge have been removed from the sludge drying beds. This is equivalent to 1.04 cu. yd. per million gallons of sewage treated.

Because of the high temperatures of the sewage due to the starch waste (70° Fahr. in winter to 104° Fahr. in summer), sludge digestion is very rapid and satisfactory all year around, even if the normal pH is as low as 6.8. At no time has there been any sludge drawn with an obnoxious odor, even when by mistake one tank was completely emptied of its sludge. Laboratory experiments with Decatur conditions have shown that at least 50% of the daily gas produced is given off from freshly deposited sludge in the first 24 hours. If the gas rate from the tanks was 100 000 cu. ft. per day and the tanks were by-passed for 24 hours, the rate would be reduced to 50 000 cu. ft. per day. This rapidity of decomposition probably explains why no foul-smelling gray sludge has ever been obtained, even by collecting a sample at the sludge line in the digestion chamber. It should be noted, however, that sludge drawn when serious foaming was taking place did not dry as rapidly as properly digested sludge, although there was present the usual "tarry odor".

The method of operating the sludge beds has been first to rake the sand smooth and then to run on from 12 to 15 in. of sludge. This sludge will dry in 10 days of good drying weather, and it is then forked into cars and dumped on low ground as fill. Considerable sludge can be taken from the beds during freezing weather. The cakes of sludge freeze to such a consistency that they are almost as easily forked as summer sludge. The sludge-bed capacity has recently been increased 41%, which will relieve the Imhoff digestion chamber of its heavy winter and spring load.

The sprinkling filter operation has been intermittent because its elevation is such that it is not operated at times of high water in the river, and because

the plant was by-passed for three months in 1926 for the construction of gas collectors and for several months in 1927 for the construction of the pre-aeration plant. Since the filters were placed in operation they have operated about 50% of the time. Table 13 gives data on a typical run from May, 1925, until January, 1926. It shows the effects of the concentration of the sewage on the filter rates, loadings, and efficiencies, particularly when high concentration and cold weather coincide. The sprinkling filter rates ranged from 1 500 000 to 750 000 gal. per day as the bio-chemical oxygen demand of the sewage ranged from 500 to 750 parts per million and the sewage temperature from 90° to 70° Fahr. At these rates the total filtering capacity of the 3 acres was from 2 300 000 to 4 500 000 gal. per day, or about one-third that necessary for complete treatment of the entire sewage. A rate of 1 000 000 gal. per day, with a bio-chemical oxygen demand of the sewage of 500 parts per million is equivalent to a bio-chemical oxygen demand loading of 4 165 lb. per acre per day.

Some trouble with ponding has been experienced. This seems to be due to growths on the surface stones and is broken up by forking, harrowing, and with water pressure from a fire hose.

TABLE 13.—SPRINKLING FILTER DATA.

Month.	Rate of application in million gallons per day.	5-day bio-chemical oxygen demand, in parts per million. The data in Table 13 show the effective removal (by the secondary tank) of bio-chemical oxygen demand from the sprinkling filter effluent. This bio-chemical oxygen demand appears to come largely from materials sloughing off the filter stones. The suspended matter removal is about 66 per cent.

*Odors.*—Very strong decomposition odors were noticeable at the inlet to the screen chamber when the plant was placed in operation. These odors were due to the relatively high temperature, which caused decomposition of the very strong sewage in the lateral and intercepting sewers. A galvanized iron railing around the screen and grit chamber was turned snow white by zinc sulfide frost. During the first few months of operation, a flap-gate was made which held these gases in the interceptor. This greatly reduced the odor during the first two years of operation.

After the diluting condenser water from the glucose plant was taken out of the sewerage system, the odors about the plant were greatly intensified, particularly at all points of turbulent flow. Analyses of the air about the plant for hydrogen sulfide showed the intensity of odor to exist in about the following order: (a) Gas from Imhoff tank gas vents; (b) above the grit-chamber effluent near the outlet weir; (c) gas from the intercepting sewer; (d) the overflow by-pass of the Imhoff tanks; (e) the dosing tanks; (f) the screen chamber; and (g) leeward of sprinkling filters during spray. These results showed the intensity of odor, but did not show the quantity. For example, the total hydrogen sulfide liberated from the 3 acres of sprinkling filters must have been very high, but the dilution with air over so great a surface makes the hydrogen sulfide concentration quite low.

The high hydrogen sulfide content of the Imhoff digestion gas was a surprise. Routine analyses of the Imhoff gas over a period of six months revealed that the hydrogen sulfide content is proportional to the temperature of digestion. Fig. 10 gives the data on temperature of digestion, percentage of hydrogen sulfide present, and the computed total pounds of hydrogen sulfide produced per day from the total Imhoff tank digestion. These data show the large amount (100 lb. per day) of hydrogen sulfide liberated at summer temperatures of digestion.

It has only been possible to obtain quantitative data on the Imhoff gas, but after considerable study of conditions a qualitative estimate indicated that, roughly, 25% of the odors came from the grit chamber, 50% from the Imhoff gas vents, conduits, and by-passes, and probably 25% from the dosing tank and sprinkling filters.

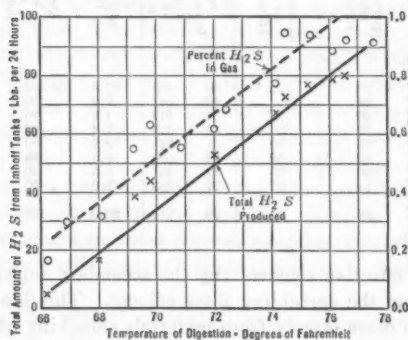

FIG. 10.—HYDROGEN SULFIDE IN IMHOFF TANK GASES, SEWAGE DISPOSAL WORKS, DECATUR, ILL.

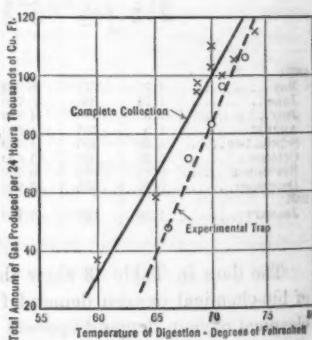

FIG. 11.—VOLUME OF GAS FROM IMHOFF TANKS, SEWAGE DISPOSAL WORKS, DECATUR, ILL.

The odors were reduced by covering the screen chamber, the grit chamber, the Imhoff tank conduits, and by-passes, and collecting all the Imhoff tank digestion gas. The chambers, conduits, and by-passes were covered with a 4 to 6-in. reinforced concrete slab containing suitable manholes and removable covers for accessibility. These covered sections were connected by 8 and 10-in. suction piping to an exhaust fan which forces the gases into a combustion

oven. The details for the collection of digestion gases are given in Fig. 4. The gas is piped to the office building for heating and laboratory use and to the combustion oven for burning, thus destroying the odors of the digestion gas and also the housed-in odors.

*Gas Production.*—Before building the gas collectors the central gas vent of one tank was experimentally trapped by building a sloping wooden structure under the surface of the sewage, somewhat resembling the Imhoff collector.\* This structure collected about one-twelfth the entire gas production. The gas from this collector was used in the laboratory and to heat the office and laboratory building during the winters of 1925 and 1926. The data regularly collected on this experimentally trapped gas were temperature of sludge digestion, volume of gas, hydrogen sulfide, calorific value, and chemical constituents. The relations of temperature to hydrogen sulfide and to total volume are shown in Figs. 10 and 11. The gas has an average calorific value of about 700 B.t.u. per cu. ft. The chemical composition varies as shown in Table 14.

TABLE 14.—CHEMICAL COMPOSITION OF GASES.

Gas.	PERCENTAGE BY VOLUME.			
	Maximum.	Minimum.	Average.	With foaming tanks.
Methane.....	74	55	68	60-64
Carbon dioxide.....	94	16	22	30-33
Hydrogen.....	4	0	2	2
Nitrogen.....	10	4	6	7
Oxygen.....	0	0	0	0

The total volume of gas from the complete collecting system has been from 80 000 to 125 000 cu. ft. per 24 hours, except when the starch works was shut down or when melting snow and cold rains lowered the temperature and, by diluting the sewage, decreased the food supply for bacterial decomposition. At such times the gas volume has reduced to about 30 000 cu. ft.

The gas and odor-collecting systems have completely destroyed the decomposition odors from the screen and grit chambers, and from the Imhoff tanks and by-passes. There is a slight sulfur dioxide odor from the burned gases, but it is not objectionable even near the oven. The sprinkling filters still give off odors when in operation which leaves the last 25% of the odors to be eliminated or reduced by the new pre-aeration plant and by recovery of waste products at the starch works. The sprinkling filters were not in operation during the summer of 1927, because of high water and the construction work for the new pre-aeration plant. During this period there have been no odors at all from the other parts of the plant, thus showing its efficiency for collecting and burning the gases.

Utilization of the gas for generation of power for the pre-aeration plant has been considered but, due to the uncertainty of the future volume and strength of the starch works sewage, it did not seem advisable to use it at

\* *Engineering News-Record*, Vol. 91, No. 13, p. 512 (1925).

present. From the analyses, about 14 cu. ft. should develop 1 h.p.-hr. in a combustion engine. The gas is to be used for heating the air for the new pre-aeration plant before compression, and is now used (1927) for heating the building, for hot water, and in the laboratory.

*Labor Force and Annual Budget.*—The labor force required to operate the plant has been an assistant chemist, a foreman, two full-time operators, a night watchman, a gardener to take care of the grounds and assist in other work, and two extra men during the sludge-drying season. The budget for the fiscal year 1926-27 for operation and maintenance of the plant is as follows:

Item.	Amount.
Supervision .....	\$4 000
Labor payroll.....	10 000
Equipment, laboratory and engineering.....	600
Materials and supplies.....	1 120
Electric power, pumping station and plant.....	2 000
Gasoline, oil, and grease.....	300
Recording gauge.....	150
Landscaping .....	1 000
Testing station operation.....	2 000
Repairs to roadways.....	200
Contingencies .....	630
Total.....	\$22 000

It is too soon to predict the cost of operating the pre-aeration plant. However, it will probably be necessary to add only one more operator to the staff. The power costs for pre-aeration have been estimated at \$15 000 per year.

*Laboratory Routine.*—Rather complete analytical data have been kept on the raw sewage and effluents, particularly because of the unusual strength of the sewage and the influence of adjustments by the starch works in its plant process or otherwise.

During 1924 and 1925 the samples were analyzed daily, but beginning in January, 1926, bio-chemical oxygen demand and nitrite-nitrate nitrogen only were determined daily; the other determinations were run on samples made by compositing 2-day samples. This method gave results which are satisfactory and allowed more time for important research work.

The regular routine analyses made were: (a) Five-day bio-chemical oxygen demand, daily on raw sewage, experiment station samples, Imhoff effluent, sprinkling filter effluent, and secondary tank effluent; (b) suspended matter, settleable matter, permanganate oxygen consumed, total nitrogen, and ammonia were determined on the 2-day composite; and (c) nitrite-nitrate nitrogen, methylene blue stability, and dissolved oxygen were determined daily on aeration testing station and sprinkling filter effluents.

All analyses are made according to "Standard Methods of Water Analysis", (American Public Health Association, 1923), except that total nitrogen was determined instead of first boiling off the ammonia and then measuring the organic nitrogen. Ammonia is determined by direct Nesslerization.

The dilution water used for the bio-chemical oxygen demand determination was from the infiltration gallery which supplies the sewage plant water system. Dr. E. R. Greenfield\* has described the importance of salts in dilution water and their effect on the 10 and 20-day oxygen demands. Dr. F. W. Mohlman recommends 0.5%  $\text{NaHCO}_3$  in distilled water. The writers favor the establishment of a definite salt-containing dilution water for the bio-chemical oxygen demand determination. The composition of the tap water which has been used after aeration and standing 20 days is given in Table 15.

TABLE 15.—COMPOSITION OF TAP WATER.  
(pH = 8.7).

Item.	Parts per million.	Item.	Parts per million.

Ammonium ( $\text{NH}_4$ ).....	0.01	Nitrate ( $\text{NO}_3$ ).....	15

Oxygen consumed from permanganate bears a very definite relation to bio-chemical oxygen demand for each sampling point, for the condition of the sample, and for the period of year. At Decatur the oxygen consumed is used as a convenient yardstick from which is predicted the probable 5-day demand on the first day.

The present Imhoff installation may be relied on to give a 65 to 75% removal of suspended matter and a 22% removal of bio-chemical oxygen demand when treating as much as 11 000 000 gal. per day. This is the maximum volume which it will handle satisfactorily.

The additional sludge bed area, making a total of 1.37 acres (equivalent to 1.0 sq. ft. per capita based on 60 000 population), will give ample sludge capacity in the Imhoff digestion chamber for the sludge from the mixed sewage. There may not be sufficient sludge capacity to take care of the waste activated sludge from the pre-aeration plant which is to be returned for digestion into the Imhoff tanks, owing largely to the uncertainty as to its volume and temperature. Separate sludge digestion tanks may have to be added later.

The sprinkling filter capacities have varied from 700 000 to 2 000 000 gal. per acre per day and from about 4 000 to 5 700 lb. of 5-day bio-chemical oxygen demand per acre per 24 hours. For an average applied sewage strength of 500 bio-chemical oxygen demand and moderate summer temperatures, the sprinkling filter will handle about 1 200 000 gal. per day and 5 000 lb. of 5-day oxygen demand per acre 6 ft. deep. During cold weather the filter rate must be cut to somewhat more than 700 000 gal. per day, in order to keep the filter in condition. The maximum nitrogen loading with Decatur sewage

seems to be about 552 lb. per acre 6 ft. deep. The 3 acres of sprinkling filters have only one-third to one-fourth the capacity required to treat the total mixed sewage without pre-aeration.

#### PRE-AERATION TESTING STATION, 1925-1926

*Purpose.*—The purpose of the pre-aeration testing station was to determine the applicability of a combination of aeration and sprinkling filters to sewage treatment at Decatur. Experience with the operation of the main sewage treatment plant indicated that a relatively large area of sprinkling filters would be needed, amounting to about 9 to 12 acres, depending on the process adjustments at the starch works. Such an increase in filter area was beyond the means of the Sanitary District and was considered hazardous from an odor standpoint.

The installation at Birmingham, England, of sewage treatment works, comprising a short period of aeration of settled sewage, with increased loading of existing sprinkling filters, looked promising. A visit to Birmingham was made, therefore, by Paul Hansen, M. Am. Soc. C. E., in 1924 and, later, by one of the Trustees of the District. The construction of the testing station as described was then recommended and authorized. Actual operation began on February 23, 1925.

*Operating Records.*—A complete record of operation is given in Table 16. The influent to the testing station comprised settled sewage from the Imhoff tanks. The volume of this influent sewage, the sprinkling filter influent, the returned sludge, and the excess sludge wasted to the sewer were all measured in orifice boxes. The volume of air used for sludge re-aeration was measured by a displacement meter. The power for operating the Simplex aerator was measured by a recording watt-hour meter. The orifice boxes for measuring the influent sewage and the liquor going to the sprinkling filters were provided with constant level overflows so that the flow through the orifice was constant. The orifice boxes for the sludge did not have constant level overflows. However, by careful attention, a close record was kept of the sludge quantities despite the difficulties occasioned by the wide variation in the density of the sludge.

The sprinkling filter was first dosed from a tank the outlet of which was controlled by a cam which opened and closed a valve in the influent line to the filter. The operation of this method of control was satisfactory, but required numerous cams for changing the rate of flow and very careful adjustment of the sprinkling filter orifice box in order not to overflow the dosing tank. The cam, therefore, was displaced by a siphon which delivered sewage to the filter at the rate at which it was pumped to the siphon tank. The air vents in so small a siphon were occasionally plugged with slimy growths so that they had to be cleaned regularly. The sprinkling filter was made of stone from the large filters and, therefore, was seeded from the beginning of the experiments.

*Operating Periods.*—The testing station was operated practically continuously from February 23 to August 20, 1925, when the motor for the Simplex aerator burned out, occasioning a shut-down until September 11. During

this time the operation was divided into ten periods, each period comprising a run of 12 to 25 days. During each of these periods the various operating elements, such as the rate of flow, the displacement period in the aeration tank, the quantity of sludge returned, and the rate on the sprinkling filters, were kept constant. During the first nine periods the sewage contained the diluting refinery condenser water which caused a weaker mixed sewage than was received later during the tests. The sewage during the tenth period was increased in strength by the removal of the condenser water and decreased by a relatively low corn grind. During these first six months of operation much was learned about the behavior of an under-aerated sewage and sludge, and this period may be designated as experimental.

Operation was resumed on September 11, 1925, and continued without any appreciable interruption until April 7, 1926. During this time there were thirteen additional operating periods each of 12 to 20 days' duration, during which the rates of flow, the aeration periods, the quantity of sludge returned, and the sprinkling filter rates were held constant; except that during Runs 11, 13, and 21, the sprinkling filter rates were varied as indicated in Table 17. The crude sewage during this period was typical of the normal strong mixed sewage without dilution by the refinery condenser water or unusual rainfall. Its strength was influenced by considerable fluctuations in the corn grind. The strongest sewage was received during the coldest weather when rates of oxidation were at a minimum and difficulties with frozen pipes somewhat interfered with continuous operation.

\* Average.

*Pre-Aeration Sludge.*—One of the major problems in the operation of the testing station was to keep the under-aerated sludge in a settleable condition.

The data in Table 16 giving settleable matter as cubic centimeters per liter, show that during the first ten periods of operation a considerable volume of sludge was discharged over the settling-tank weirs on to the sprinkling filter. The relatively light character of this settleable matter is indicated by the proportionately lower quantities of suspended matter. During these periods the sludge was very thin and often would not settle appreciably in 2 hours. This thin fluffy condition of the sludge was first attributed to a lack of sufficiently heavy solids in the settled influent to the aeration tank, and attempts were made to procure a thicker sludge by (a) returning a larger percentage of sludge to the aeration tank; (b) increasing the period of sludge re-aeration to 5 hours; and (c), increasing the aeration period to 7 hours. None of these methods was entirely satisfactory. Increasing the quantity of returned sludge made bulking worse; and increasing the time of sewage aeration and sludge re-aeration, within the limits used, had no appreciable effect. It was finally found that each period of aeration and its strength of sewage gave a characteristic sludge which could be maintained and settled if not more than about 10% by volume of sludge after setting 1 hour was kept in the aeration tank liquor.

Operating experience clearly indicated that sludge should not be allowed to remain or accumulate in the settling tank. The solution of the sludge-handling problem appears to be a prompt and regular drawing of sludge so as to maintain only relatively fresh sludge in circulation as shown during Periods 17, 18, 19, and 20, in Table 16. During Periods 17, 18, and 19, the sludge was black, flocculant, with a rather septic odor, and settled rapidly. During Period 19 a considerable quantity of sludge was lost because of frozen sludge pipes. Just before the start of Period 20 the sludge line broke and all sludge was lost so that during this period the operation of the aeration tank was with entirely fresh sludge. The removal of 5-day bio-chemical oxygen demand by the partial aeration during these periods was, as follows:

Period.	Percentage removal of 5-day bio-chemical oxygen demand.
17 .....	32
18 .....	34
19 .....	44
20 .....	53

Thus, with the fresher sludges the removal of bio-chemical oxygen demand was greater.

*Settling Tanks.*—With partial aeration, the condition of the sludge makes the capacity and rating of the settling tanks important. In the testing station, the sludge was satisfactorily settled with a displacement period of 1.1 hours and a surface rating of 1 050 gal. per sq. ft. per 24 hours. When severe bulking of the sludge took place, it could not be settled with the maximum available displacement period of 3.6 hours equivalent to a surface rating of 320 gal. per sq. ft. per 24 hours. With regular and sufficient removal of the excess, the sludge may be kept sufficiently fresh and active and in condition to permit satisfactory sedimentation. This active sludge is in no way a typical activated sludge from complete aeration works, except in the

physical nature of the floc. The color is gray to black and not brown. The odor is disagreeable, but not septic. The operation of the testing station indicated that the volume of sludge in the aeration tanks should not be more than 10% by volume as determined by sedimentation in cylinders for 1 hour. If a poorly settled sludge is developed, the best procedure is to remove it and to start again building up a new sludge. This is often almost white, but becomes more gray in color each day.

*Periods of Aeration.*—The period of aeration has a very definite relation to the amount of purification as measured by the percentage removal of bio-chemical oxygen demand. Fig. 12 shows the reduction in the 5-day bio-chemical oxygen demand for different periods of aeration. Although the longest aeration period was 11.2 hours, the trend of the operating data indicated that about 16 hours might be required for complete treatment of the Decatur sewage after preliminary sedimentation in order to turn out an effluent containing sufficient nitrates to insure stability with maintenance of a satisfactory sludge.

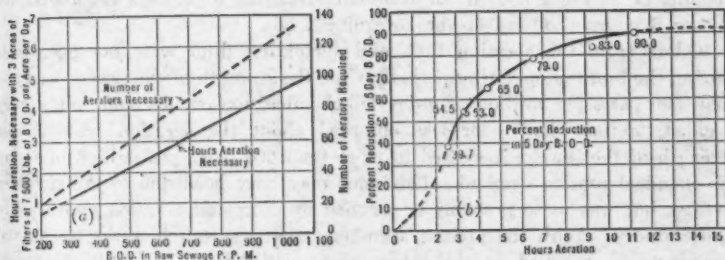

FIG. 12.—PRE-AERATION REDUCTION IN BIO-CHEMICAL OXYGEN DEMAND, SEWAGE DISPOSAL WORKS, DECATUR, ILL.

The maximum capacity of the testing station permitted only 6 hours re-aeration of the returned sludge. Under Decatur conditions this re-aeration did not materially improve the quality of the sludge. It was considered that a larger capacity in the pre-aeration tanks was preferable to provision for sludge re-aeration. In the full-sized plant connections have been made for the later construction of sludge re-aeration tanks should they be found desirable. The testing station operation showed that 6 hours of sludge re-aeration are of little value.

*Operation of Sprinkling Filter.*—The results of operating the small sprinkling filter are shown in Table 17. These data indicate that on a filter 6 ft. deep, about 7 500 lb. of 5-day bio-chemical oxygen demand can be satisfactorily handled per acre per 24 hours. It may be possible to handle a larger quantity than this at summer temperatures. This loading, under Decatur conditions, represents a dose at the rate of between 2 500 000 and 3 500 000 gal. per acre per 24 hours.

Table 16 gives the removal of 5-day bio-chemical oxygen demand by the several parts of the plant. From crude sewage to sprinkling filter effluent the removal of 5-day bio-chemical oxygen demand was, in general, somewhat

more than 90 per cent. The testing station included no secondary or final settling tank for the sprinkling filter effluent. By such sedimentation, the bio-chemical demand of the sprinkling filter effluent may be further reduced from 20 to 50% of the final settling tank influent, thus increasing the over-all removal of bio-chemical oxygen demand to about 95 per cent.

Studies at the testing station showed that within reasonable limits, the sprinkling filters could be operated at a relatively constant loading of 5-day bio-chemical oxygen demand (in the partly aerated sewage) amounting to 7 500 lb. per acre per 24 hours. Thus, the quantity of effluent delivered to the sprinkling filter was proportionate to its strength and was fixed at about 22 500 lb. of bio-chemical oxygen demand for the 3 acres. It is possible, therefore, to draw a rough balance between the amount of pre-aeration necessary for any given strength of sewage with the 3 acres of sprinkling filters. Such a computation would include the over-all annual costs reflecting the fixed charge for construction and the annual cost of power and labor, so that the best economy for each condition might be secured. Fig. 12 gives the amount of aeration needed for different strengths of sewage calculated for dosing 3 acres of filters at the foregoing loads.

Odors from the aeration tank and sprinkling filter were not noticeable during the first ten operating periods, while the strength of the sewage was less than 500 parts per million of 5-day bio-chemical oxygen demand, but a very decided "animal den" odor was observed about the aeration tank as the strength of the sewage increased to more than 600 parts per million of 5-day bio-chemical oxygen demand. This odor may have been due to the stronger sewage, but was more probably occasioned by decreased aeration and a more septic sludge. With the process adjustments at the starch works the mixed sewage to be handled in the larger plant will have a 5-day bio-chemical oxygen demand of about 300 parts per million. With this weaker sewage, the new plant is not expected to give off any objectionable odors.

*Basis of Design, New Pre-Aeration Plant.*—The design of the new pre-aeration plant is based on a dry-weather sewage flow of 10 000 000 gal. per day and a maximum rate of 16 000 000 gal. per day, with additional capacity in the aeration tanks for 10% of the returned sludge. Analyses of the starch works sewage and the city sewage indicate that after the process adjustments at the starch works the mixed sewage will have a 5-day bio-chemical oxygen demand of somewhat more than 300 parts per million. Fig. 12 indicates that a sewage of this strength will require pre-aeration for about 1.95 hours to prepare it for application to the existing 3 acres of sprinkling filters. Because of possible irregularities in the starch works sewage and because of the retarding effect of cold and wet weather, it was decided to give the aeration tanks a displacement period exclusive of returned sludge of 2.75 hours, when the sewage flow was 10 000 000 gal. per day. This is equivalent to 1.56 hours at the higher rate of 16 000 000 gal. per day.

The settling tanks were also designed on a relatively conservative basis so that occasional sludge, difficult to settle, can be better recovered. Therefore, a displacement period of 2.6 hours, equivalent to a surface rating of 833 gal. per sq. ft. per 24 hours, was adopted. These capacities are about twice those found desirable during the test periods, 11 to 20 (Table 17).

## PRE-AERATION PLANT, 1926-1927

*General Arrangement.*—After the testing station had been put in operation plans were prepared and contracts let for the construction of a pre-aeration plant with a rated capacity of 10 000 000 gal. per day. The plant comprises aeration units, settling tanks, blower house, and appurtenances; and brings the capacity of the sewage disposal works to about 150 000 equivalent population.

During the operation of the pre-aeration testing station, conferences were held with the officials of the starch works relative to process adjustments within the starch plant looking toward a reduction in the strength of the sewage. At that time the organic matter in the starch works sewage was roughly indicated, as follows:

Plant.	Pounds of total organic and free ammonia nitrogen in starch works sewage per bushel of grind.
Argo .....	0.06
Pekin .....	0.02
Decatur .....	0.14

The officials of the starch works at Decatur agreed to make process adjustments in their plant. At the time of the conferences in 1926, the equivalent population of the starch works sewage had, at times, exceeded 300 000. It was agreed that process adjustments would be made in the starch works so as to reduce the population equivalent to about 90 000 by July 1, 1927; and thereafter to a population equivalent of about 1 000 for each 1 000 bushels of corn ground and at a rate to keep pace more or less with the growth of the city. The Sanitary District agreed to install a pre-aeration plant to bring the capacity of the disposal works up to about 150 000 by July 1, 1927. Both agreements have been fulfilled except as to time, which was extended about four months. Thus, the Sanitary District in effect provides a somewhat liberal capacity for its future requirements and permits the starch works to utilize the available capacity for the future.

The pre-aeration plant has been built east of the present sprinkling filters, in the west end of the space allotted to future sprinkling filters in the original layout. The new blower house stands between the aeration tanks and the sprinkling filters. Along the east side of the new settling tanks, space is reserved for sludge re-aeration tanks should they be found desirable; and, in general, future extensions of the pre-aeration plant are planned in an easterly direction.

In order to provide head for the new units, it was not considered necessary to raise the elevation of the flow line in the Imhoff tanks, although this was possible because of the contingent allowance of 1.0 ft. in the original design and the relatively ample free-board of 23 in. The operating level of the dosing tanks however, was adjusted from Elevation 601.90 to Elevation 601.25, thus providing a head of 1.36 ft. for the operation of the pre-aeration plant. The hydraulic computations were based on a maximum rate of sewage flow of 16 000 000 gal. per day, an average of 10 000 000 and a minimum of 8 000 000 gal. per day.

*Aeration Units.*—There are six aeration units each 120 ft. long, 16 ft. wide, and 14.5 ft. liquid depth over the aeration plates, with 14 in. of free-board. Including an allowance of 10% for returned sludge, the aeration tanks have a displacement period of 2.5 hours with a sewage flow of 10 000 000 gal. per day.

The aeration provides spiral flow from two rows of filter plates along one side of each tank (the so-called Manchester type), the plate area amounting to 10.65% of the tank area.

An inlet conduit extends along the north end of the six tanks from which the sewage flows into the center of each tank through 24 by 24-in. sluice-gates. Return sludge is pumped into the sewage at the inlet or west end of this conduit. The aerated sewage flows out of the tanks over weirs and then through Venturi meters to the settling tanks. There is one Venturi meter for each two aeration tanks so that the sewage flow can be distributed as desired. Indication of this flow is carried by air to the sludge pump houses. A pipe gallery extends along the south end of the aeration tanks, with a sludge pump house at the southeast end of the gallery housing the Venturi meter indicators, valves, piping, and sludge pumps, and connecting directly with the blower house at the west end.

There are two settling tanks each 77.5 ft. square, with a liquid depth of 10.37 ft. at the periphery and 13.69 ft. at the center. The total displacement period above the sloping bottom is 2.6 hours and the settling rate is 833 gal. per sq. ft. of tank surface per 24 hours, both for a sewage rate of 10 000 000 gal. per day.

The sewage will enter the tanks from a conduit along their east sides through six inlets for each tank. The effluent is discharged over adjustable weirs extending along the entire width of each tank and into a conduit connected to the dosing tank.

Each tank is equipped with a Dorr mechanism for the removal of sludge. The sludge passes through an 8-in., cast-iron pipe built under the tanks to an open well at the east end of the pipe gallery. Two 8-in. centrifugal pumps send the sludge either to the main conduit leading to the Imhoff tanks or to the conduit leading to the aeration tanks. There is a Venturi meter for each sludge line, and the division of flow is controlled by gate valves in the sludge lines.

The blower house is 50 ft. long by 26.5 ft. wide inside and has space for four blowers, a boiler for heating the air, and other appurtenances. There are two gear-connected General Electric blowers of the centrifugal type, operating at 11 850 rev. per min., each having a capacity of 3 500 cu. ft. of free air per min. At the average sewage flow of 10 000 000 gal. per day, this is an installed capacity equivalent to about 1.0 cu. ft. of air per gal. of sewage.

The characteristic curves of this type of blower are shown in Fig. 18. Curves *A*, *B*, and *C* are based on air temperatures of 35°, 50°, and 95° Fahr., respectively, and barometric pressures of 14.85, 14.4, and 14.0, respectively. With one blower in operation, the rate of air delivery can be varied from about 0.4 to 0.6 cu. ft. per gal. of sewage, with very little loss in efficiency.

The characteristic curves show that for equal volumes of free air, the warmer the air the less the power required. In view of the fact that considerable gas from the Imhoff tank was available, it was considered advisable to maintain the air going to the blowers at a temperature of about 95° Fahr. The air is drawn through louvres in the blower-house wall, through thermostatically controlled steam-heating coils, through a cell-type air filter, and thence to the blowers. The coils have a capacity to raise 3 500 cu. ft. of air per min., about 70 to 100° Fahr., depending on the temperature of the incoming air. The coils are supplied with steam from the blower-house steam-heating system. The cell filters have a capacity of 7 500 cu. ft. per min.

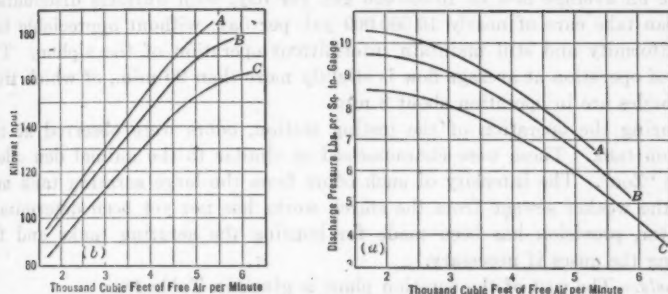

FIG. 13.—CHARACTERISTIC CURVES OF CENTRIFUGAL COMPRESSOR, SEWAGE DISPOSAL WORKS, DECATUR, ILL.

Air deliveries will be measured through a Bailey meter in the blower house on the main 18-in. cast-iron air line. This air line passes through the pipe gallery with 10-in. branches to each aeration tank and a 4-in. branch to all conduits. The rate of air flow to the three 10-in. and one 4-in. air lines is indicated in the sludge pump house by manometers which indicate the differential across the flow nozzles inserted in the several air lines. In this way, the flow in all the branches may be readily distributed by suitable adjustment of the valves. The air lines are provided with condensate traps for the removal of water. The blower house is built of common brick on a concrete foundation and has an asphalt shingle roof.

Excess sludge is pumped into the crude sewage near the bottom of the riser conduit at the northeast corner of the Imhoff tanks. The excess activated sludge is thus being digested with fresh sludge in the lower compartments. With the reduced strength of the starch works sewage, it is expected that there will be sufficient sludge digestion capacity in the present tanks to handle the excess activated sludge. Within a few years, however, it is planned to increase the sludge digestion capacity by adding separate sludge digestion tanks.

The operation of the testing station indicated the possibility of running the sprinkling filters at a rate of 3 000 000 gal. per day per acre. Therefore, it was necessary to increase the capacity of the dosing tanks, to install additional siphons, and to put in many more nozzles.

With the original installation of dosing tanks and 860 nozzles for the 3 acres of filters, the maximum rate of dosing was about 2 500 000 gal. per day

per acre, or a total of 7 500 000 gal. per day, without putting the siphons into continuous operation. The nozzles were originally of the Taylor circular spray type with 1½-in. orifices spaced at 13 ft. 3 in., center to center. They were replaced with 1312 Taylor circular spray nozzles with ¾-in. orifices spaced at 8 ft. 10½ in., center to center. The original system of distribution piping was used, and the additional nozzles were installed by means of branch pipes from the taps already made in the lateral distribution. The closer spacing and greater number of nozzles allowed a lowering of the high-water level in the dosing tank of 0.65 ft., which was made available for the pre-aeration plant.

The remodeled dosing tanks and filter distribution system are designed to handle an average flow of 10 000 000 gal. per day, with uniform distribution and can take care of nearly 16 000 000 gal. per day, without appreciable loss of uniformity and still maintain intermittent operation of the siphon. The cycle of operation at average flow is slightly more than 20 min., of which time the nozzles are in operation about 8 min.

During the operation of the testing station, odors were observed at the aeration tank. These were characterized as similar to the animal den odors at the "Zoo". The intensity of such odors from the large aerating tank and with the weaker sewage from the starch works has not yet been determined. However, provision has been made for housing the aerating tanks and for burning the gases if necessary.

*Costs.*—The cost of the aeration plant is given in Table 18.

TABLE 18.—COST OF AERATION PLANT.

Item.	Amount.
Contract 5.....	\$142 735.71
Blowers.....	16 000.00
Switchboard.....	3 397.00
Oil filter equipment.....	496.09
Air meter.....	943.00
Air filter.....	295.00
Aeration plates.....	2 800.00
Dosing tank equipment.....	2 550.00
Additional piping.....	1 351.35
Blower house.....	44 063.00
Wrecking dosing tank.....	1 100.00
Total.....	\$216 381.06

The unit prices of the major items were stated in the contract as follows:

Earth excavation .....	\$0.50	per cu. yd.
Rock excavation.....	5.00	" " "
Reinforcing steel.....	0.053	per lb.
Concrete in floors and footings.....	12.25	per cu. yd.
Concrete in walk and conduits.....	20.00	" " "
Miscellaneous steel and wrought iron.....	0.13	per lb.
Miscellaneous iron castings.....	0.13	" " "
Cast-iron pipe, bell and spigot.....	0.037	" " "
Cast-iron specials, bell and spigot.....	0.093	" " "
Cast-iron specials, flanged .....	0.132	" " "
Subway grating .....	1.65	per sq. ft.

## CONCLUSION

The project at Decatur up to the final stages of operation has required nearly fifteen years of investigation and construction effort. Portions of the work, such as the organizing of the Sanitary District, and the treatment of the starch works sewage, were unusual and required careful and gradual working out. The persistence of the effort is noteworthy and is due in large measure to the continued service of the Board of Trustees, one of whom has remained throughout the entire life of the Sanitary District. It is the hope of the writers that the foregoing record will be useful in the consideration of other sewage disposal problems.

## DISCUSSION

GEORGE W. FULLER,\* M. AM. SOC. C. E.—Among the novel features of the Decatur plant, pre-aeration perhaps comes first to mind as this is one of the first instances in America where that arrangement has been studied. It became a factor in respect to cutting down the load on the sprinkling filters. That plan of course has been studied in Europe in a few instances, particularly at Birmingham, England, where it has enabled the doubling of the load on the filters when it was found difficult to increase the available area or to get more money for construction. One hour is the period of pre-aeration at the Birmingham Plant and a portion of the excess sludge is aerated and conditioned in a tank. This provides about 16 to 18 hours of flow.

This pre-aeration may be applicable in places where ordinary sedimentation would be sufficient for perhaps twelve months in most years, but where occasionally there may be need, for a few months of very dry weather, of something beyond ordinary sedimentation. This idea relates to pre-aeration as a device for removing colloidal matter, not as a nitrate producer and not as a reducer of dissolved organic matters. There are plants, perhaps, like the one at Columbus, Ohio, at which advantage is taken of the diluting effect of stream flow available for a number of months of the year, and where during periods of low stream flow, there should be more treatment than is afforded by ordinary sedimentation.

Another arrangement serving the same general purpose is what Karl Imhoff, M. Am. Soc. C. E., calls contact aerators. These are used in half a dozen plants in the Ruhr District, in Germany, to get a better removal of the organic matter than is possible by sedimentation. After flowing through those tanks, the sewage goes along the stream bed a short distance to the Rhine. During this travel the mixed Ruhr water and treated sewage become well aerated. However, the colloids caused official complaint from across the National Boundary in Holland where the fishermen complained bitterly of fungus growths interfering with their nets.

Whether pre-aeration as described by the authors as a means of lessening the load on the sprinkling filters is a better arrangement than contact aerators, the speaker does not know. It certainly suggests possibilities for the solution of some types of problems.

The pioneering aspects of the Decatur plant are interesting as regards the collection and burning of gas to eliminate odors. That is an important step in advance. The observations in the paper as to lime also impress the speaker because of experiences recently with efforts to handle some of the complications which arise at intervals with Imhoff tanks, particularly at a plant that went in service in the fall of 1926 at Newcastle, Pa.

After some months of operation during the winter, when no effort was made to increase the temperature of the sewage or sludge, there was a tremendous amount of foaming followed by acid production in the spring. This acidity was not materially affected by the addition of small doses of lime. About

\* Cons. Engr. (Fuller & McClintock), New York, N. Y.

ten years ago, at Plainfield, N. J., acid production became so pronounced that additions of lime were almost futile. When the pH-value becomes considerably less than 6, say, 5.2, the addition of lime in small quantities is not effective. The only recourse is to put in sufficient lime to bring the pH-value up to about 7, or more.

The question of handling gas at Newcastle has proved bothersome in that the arrangements for collecting it were improvised after the contract had been let, and they permitted the clogging of the gas screens. A further complication resulted from the large quantity of scum. While the gas collector is submerged, nevertheless its arrangement permits the space beneath the gas exits to fill with floating matter, so that the original facilities for cleaning it are now inadequate. Hence, at that plant there were three problems: (1) Inadequate screening provided by 2-in. clear openings; (2) inadequate protection of the gas exits which could be improved by the use of gas screens that do not clog so readily; and (3) inadequate arrangement for flushing the scum that accumulates in the A-space beneath the covers of ordinary gas vents, which covers have a longitudinal slope to lead the gas to the several screened exits.

JOHN F. SKINNER,\* M. AM. SOC. C. E.—This paper is very interesting and the speaker wishes to add a few words on one point that is based on recent experience in Rochester, N. Y. A section of that city is supplied with water from Lake Ontario by the Rochester and Lake Ontario Water Company. This water is coagulated, passed through pressure filters, and chlorinated.

The Water Company's intake is 1.5 miles west of the mouth of the Genesee River and an occasional east wind carries to the intake a current of river water polluted with sewage and industrial wastes. The plant of the Rochester Gas and Electric Corporation has been in the habit of discharging into the river, 8 miles from its mouth, an average of 20 000 gal. per day of ammonia-still waste containing about 350 lb. of phenol ( $C_6H_5OH$ ). Whenever the polluted river water reached the intake, the chlorine dose was increased, and complaints of the taste were numerous.

It was thought that if this gas-house waste could be discharged into the city's intercepting sewer, passed through the main disposal plant (consisting of Imhoff tanks), and then discharged with the effluent into Lake Ontario, 7 000 ft. from shore, in water 50 ft. deep and 2 miles farther from the water-works intake than the mouth of the river, greatly increased dispersion would take place, and if the waste reached the water-works intake it would be greatly diluted.

In order to determine whether this waste could be safely handled in the tanks at the main plant without upsetting their action and their ability to digest sludge properly, a large-scale experiment was conducted at the City's small "Charlotte" Plant† where the discharge averaged 500 000 gal. daily. The Imhoff tank has an inside diameter of 38 ft. In this tank the sewage flow is semi-circumferential, and a steel dome was placed over the central opening and

\* San. Engr., City of Rochester, Rochester, N. Y.

† Transactions, Am. Soc. C. E., Vol. 91 (December, 1927), p. 524.

its lower edge sealed by setting the dome in an annular groove of concrete on the deck and filling this groove with water.\*

The experiment was begun on June 3, and ended on September 2, 1927. Physical and chemical constants were first determined from four samples of normal sludge and later these were compared with fourteen samples of sludge after the continual addition of ammonia-still waste. The ratio was 1 gal. of waste to 1 000 gal. of sewage, or 500 gal. of waste daily, containing about 8.75 lb. of phenol, to 4 166 000 lb. of sewage, or 2.1 parts of phenol per 1 000 000 parts of sewage by weight.

The conclusions from the experiment were that when phenol wastes are added to sanitary sewage at a concentration of 2 parts per million of phenol, no harmful effects result. The operation of the Imhoff tank can be carried on as usual and the digestion of the sewage solids takes place rapidly and energetically. This was indicated by the following facts:

- 1.—The sludge was well digested and drained quickly on the drying bed.
- 2.—No change in physical constants resulted, except a high and clear dewatering.
- 3.—Chemical constants indicated a better stabilization and more complete digestion.
- 4.—Bacterial population showed an increase for both aerobic and anaerobic.
- 5.—Chemical analysis of dry sludge and ash showed small variations from normal sludge.
- 6.—The pH-value was normal.
- 7.—A high rate of gas, which was mainly methane (about 70%) and CO<sub>2</sub> (about 30%) resulted. The calorific value was 700 B.t.u.

The entire discharge of the Rochester Gas and Electric Corporation's ammonia-still waste into the sewer leading to the (main) Irondequoit Disposal Plant† is at a lower concentration than that of the experiment. The plan has been put into operation, no upsetting of the plant has occurred, and all complaints of taste in the water have ceased.

SAMUEL A. GREELEY,‡ M. AM. SOC. C. E., AND WILLIAM D. HATFIELD,§ Assoc. M. AM. SOC. C. E. (by letter).—The pre-aeration unit of the treatment plant at Decatur, Ill., went into operation on December 30, 1927, and a discussion of the records during the first months of 1928 is a fitting closure to the paper. The weighted operating data in Tables 19, 20, and 21 and in Fig. 14 show the efficiencies obtained by each step in the process, and the chemical content of the effluent. In Table 19, the population equivalent is the product of the 5-day biochemical oxygen demand and the sewage flow, multiplied by  $\frac{8.33}{0.17}$ . The factor, 0.17 lb. of bio-chemical oxygen demand per capita per 24 hours, has not been confirmed by independent data at Decatur, but has been accepted from the

publications of the U. S. Public Health Service and others. On a few occasions during shut-downs at the starch works the indications are that this figure is reasonably correct and applicable to Decatur. The percentage removals in Tables 19, 20, and 21, represent the total up to, and including, the treatment indicated in the column under consideration, that is, the indicated efficiency under sprinkling filters includes the removal of the Imhoff tanks plus the pre-aeration tanks plus the sprinkling filters. The percentage removal in each case is computed starting with the total population equivalent received at the treatment plant and not that actually carried through the processes. Thus, sewage by-passed during the first months of the record lowered the resultant efficiency accordingly.

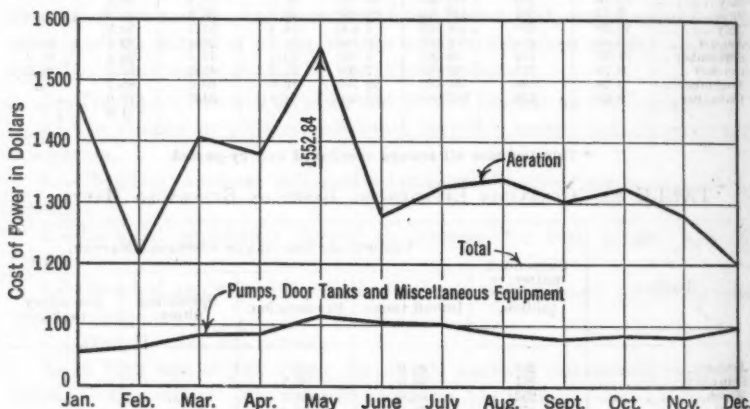

FIG. 14.—COST OF POWER FOR THE YEAR 1928.

The population equivalents of the sewage received at the plant from January through April show a gradual decrease in starch plant waste, due to more careful operation of the old process of manufacture. On April 28, the new waste recovery system went into operation. Up to this time, the pre-aeration plant (150 000 population equivalent capacity) was overloaded and was treating only a part of the sewage. This accounts for the lower efficiencies of the pre-aeration and sprinkling filter units during the early months of operation. Beginning with May, the population equivalent dropped to about 120 000, or less, and the efficiencies thereafter were satisfactory as shown by the data.

In November and December a decreased pre-aeration efficiency may be attributed to numerous factors, including lower temperatures, greater losses from the starch works, and especially the fact that one-third of the pre-aeration plant was used for sludge re-aeration. The re-aeration of return sludge varied from 9 to 18 hours and is still being studied.

The reduced sprinkling filter efficiency in November was due to the heavier loading because of stronger sewage and lower pre-aeration efficiency, while that in December was due to the fact that the filters were operated only 20 days because of high river stages. The actual efficiency of the filters during the 20

days of operation was 91%, while the over-all weighted efficiency for the 31 days was 73 per cent.

*Summary.*—Experience to date leads the writers to expect the following efficiencies at the Decatur treatment plant as now operated: (a) The Imhoff tanks remove from 20 to 25% of the bio-chemical oxygen demand; (b) pre-aeration raises this percentage removal to from 45 to 50; and (c) the sprinkling filters at 3 300 000 gal. per acre per day and secondary sedimentation further raises this removal to from 85 to 95 per cent.

The final effluent will average around 60 parts per million of suspended matter, 6.0 to 12.0 parts per million of nitrates, 3.0 parts per million of dissolved oxygen, and a stability usually greater than 90 per cent.

### WATER SUPPLY PROBLEMS OF A DESERT REGION\*

BY WILLIAM E. RUDOLPH,† M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. LEWIS R. EAST AND WILLIAM E. RUDOLPH.

#### SYNOPSIS

This paper treats of some of the water supply problems of a section of the Atacama Desert of Northern Chile—the sources of water, the nature of the waters and the losses to which they are subject, and the works which have been installed for impounding and transporting water: Some notes are added on the utilization of surplus water resources for irrigation and for hydro-electric power, presenting conditions peculiar to arid regions.

#### GENERAL

The water supply problems of desert regions are peculiar. Not only is precipitation scant in these arid lands, but the losses of water from evaporation and seepage, as well as contamination by absorption of salts, are factors which seriously affect the available supply.

Desert regions comprise nearly one-quarter of the land surface of the earth. Some have developed considerable economic importance through the discovery of mineral deposits which the very aridity of the climate has preserved. Among the latter is the Atacama Desert of Northern Chile, where the world-famous nitrate fields are located, and also important bodies of copper ore. Here, a number of inland industrial centers have grown up, as well as several prosperous seaports, among the latter being Antofagasta and Iquique, cities of more than 50 000 population.

#### SOURCES OF WATER OF THE ATACAMA DESERT

Situated between two rain barriers, the Humboldt current and the Western Cordillera of the Andes, Northern Chile has little rainfall. At elevations

\* Published in October, 1928, *Proceedings*.

† Chf. Engr., Green-Muth Bldg. Corporation, Rockville Center, N. Y.

below 10 000 ft., it averaged only 0.04 in. per year prior to 1925.\* It is little wonder that the Desert of Atacama is one of the most barren of the earth's surfaces.

Above an elevation of 10 000 ft. there are light showers during the summer (January to April) of most years. A single stream reaches the Pacific throughout the year—the Rio Loa (Fig. 1)—which has a maximum flow of 130 cu. ft. per sec., decreasing to 67 cu. ft. per sec., as it crosses the desert (Table 1). Yet this little stream supplies the Antofagasta nitrate pampa, the copper plant at Chuquicamata, and the City of Antofagasta, and contributes to the operation of three railroads and to the irrigation of farm lands.

In this latitude the Andes form two distinct ranges, the Cordillera Occidental and the Cordillera Oriental. Separating them is a region of high plateaus without surface drainage. The strip of land sloping to the Pacific, as well as portions of the high plateaus, form part of Chile.

The Cordillera Occidental (Fig. 1) consists of a uniformly high surface of folded and uplifted rocks, upon which volcanic masses have formed peaks and ranges. After the main range of the Cordillera Occidental had been raised to its present height, the forces of volcanism appear to have shifted toward the west, where subsidiary and lower chains of volcanic cones were built up. In but few places did they cut off drainage to the Pacific, but they did cause the formation of large lakes which gradually filled up with sediments, in some places to depths of perhaps 2 000 ft.

The waters which feed the Loa System originate primarily from summer snows and rains which fall in the high Cordillera region. These form a number of small streams (Fig. 2), most of which flow only during the heat of the day. The streams disappear within the sediment-filled lakes. Along the western bounds of these basins, at the lower points of the secondary ranges, the waters emerge as springs (Fig. 3), below which they have cut deep spectacular canyons through the volcanic formations to the lands beyond. By acting as natural reservoirs, the basins regulate the tributaries of the Loa and thus maintain a fairly constant flow throughout the day, season, and year.

East of the main range of the Cordillera Occidental are a number of wet basins without apparent outlet. Although subject to heavy evaporation, the lakes never dry up, for their water-sheds, being reached by moist east winds, experience no prolonged droughts. As they lie well above the Pacific draining region on the western side of the intervening range, there must be drainage from one to the other, probably along contacts of the older rocks and the newer volcanic topping which form this range. Thence, the subterranean waters flow directly into the basins of sediments, from which the streams of the western slopes draw most of their water. Thus, it would appear that the streams draining to the Pacific are fed from waters of the moister eastern slopes even when their local supply fails.

#### STREAM FLOW MEASUREMENTS

Recording stream flow in the Atacama Desert, particularly at the headwaters of the feeders, was a work fraught with difficulty. Changes in river

\* During the years 1925, 1926, and 1927, the rainfall has been greater, due perhaps to the supplanting of the cold northbound Humboldt current by the warmer southbound El Nino current during the summer of 1925. Such change in climate is probably of a transient character.

beds caused by flood flows permitted leakage at the sides and below weirs. Several times complete destruction followed cloudbursts. At current-meter stations the configuration of the river bed was so often subjected to alteration by high water that constant checking was necessary during the rainy season.

Observation stations were of necessity located in isolated regions, a day's muleback journey apart in many cases. Food and shelter were poor, the only inhabitants being in a few Indian pueblos. These Indians were always friendly, although the diversion of water would have been disastrous to them. The cold of the Cordillera is intense at night, whatever the season, and "soroche", or mountain sickness, was a further severe handicap to men who were not accustomed to high altitudes. The native observers placed at stations had their limitations, and supervision was both difficult and expensive.

## VARIATIONS IN FLOW

Flow in the streams fed from underground reservoirs varies but little. For example, during 1913 monthly averages of flow in the Rio Loa just below the confluence with the Rio San Pedro remained between 56 and 62 cu. ft. per sec. Over a period of  $3\frac{1}{2}$  years, the limits of monthly averages were 54 and 71 cu. ft. per sec. The increases during the summer months from rains are not great. Sudden floods are occasioned by cloudbursts and heavy storms,

but high water seldom lasts for more than 3 or 4 hours. In February, 1925, the volume of the Loa below the confluence with the Salado, near Chiu-Chiu, rose to more than 15 000 cu. ft. per sec. for a few hours, this being 115 times the normal flow and probably the highest in the recent history of the river.

During the irrigating season, from September to March, losses of water in the Loa below Chiu-Chiu are heavy, as may be seen from the minimum normal flows in Table 1.

#### LOSSES OF WATER

The flow and usability of waters of the region suffer from (1) losses from evaporation; (2) losses from seepage; and (3) absorption of salts. These three important factors will be discussed separately.

*Evaporation.*—Waters which enter interior drainage basins, mere evaporating pans, are lost in evaporation. Flows of the Loa and other river systems are also subject to high evaporation whenever they spread out to form marshes. Where water-works have been installed, the construction of narrow masonry canals to drain these swamp lands, or to carry the waters past them, has been necessary.

The magnitude of these losses is due in part to the extreme dryness of this region. Comparison of the evaporation observed in the Atacama Desert with that given by Ivan E. Houk, M. Am. Soc. C. E., for U. S. Reclamation projects (Table 2) show that rates in the Chilean desert are generally higher than at Yuma Citrus, Ariz., the driest of Mr. Houk's stations. While the writer's data were compiled partly by the Chilean Government and partly by industrial companies, and, therefore, probably are not of the same high degree of accuracy as those of Mr. Houk, they are nevertheless significant.\* The stations at Chacance and Chuquicamata are representative of the arid sections of the Atacama Desert.

Eventually, the water requirements of the Northern Chilean desert may necessitate complete drainage of the lakes on the Bolivian side of the frontier, by means of tunnels, to avoid evaporation losses. The costs of such works are not so apt to be a drawback as the international complications.

*Seepage.*—So numerous are the lava flows which have obstructed drainages and diverted them from one course to another that a detailed study of such formations may be necessary in order to determine the origin of a particular flow. Streams disappear below the surface and, later, re-appear, sometimes greater in volume, sometimes less. That underground flows are often large in quantity has been demonstrated by the increases observed in stream flow at sections where no run-off is received. Isolated water holes, oftentimes in the most arid parts of the desert, furnish further proof of such underground flows. On the face of the Coastal Range escarpment beside the Pacific, where the strata have been exposed by fracture, springs are frequent—although this is a region where showers occur perhaps once in a year. Part of the flow

\* None of the Chilean observations was based on the use of floating pans. Inasmuch as the high evaporation rates of the Atacama Desert are due to high average wind velocity rather than to high average temperature, it would seem that there would be far less difference between land and water-pan measurements in this case than at the stations mentioned by Mr. Houk.

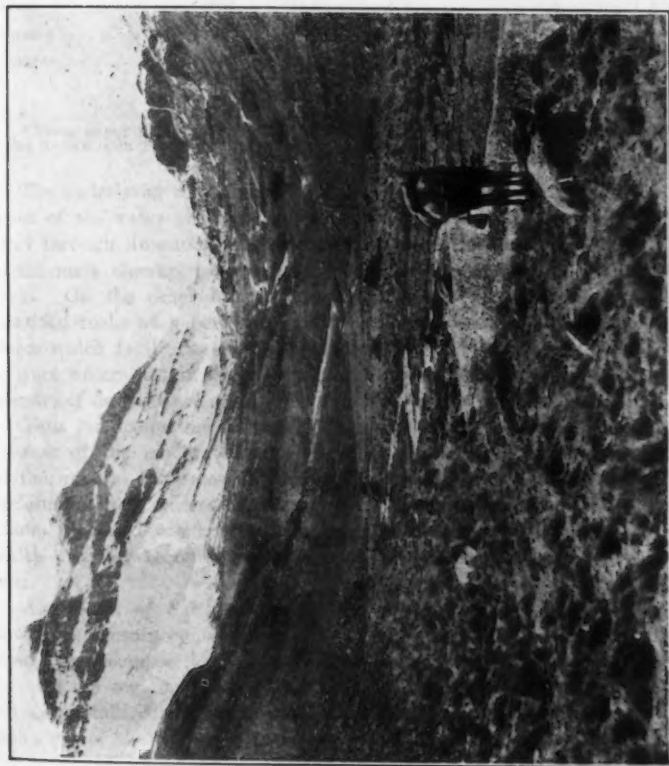

FIG. 2.—VIEW OF SMALL STREAMS ORIGINATING FROM SUMMER SNOWS AND RAINS IN THE ANDES IN CHILE.

FIG. 3.—UNDERGROUND FLOW EMERGING AS SPRING IN THE ANDES IN CHILE.

of these springs is doubtless due to condensations from the afternoon clouds which envelop the coastal cliffs, but more, perhaps, comes from underground passages extending a hundred miles or more inland to the Cordillera region.

TABLE 2.—COMPARISON OF EVAPORATION RECORDS OF UNITED STATES RECLAMATION PROJECTS\* AND OF ATACAMA DESERT, CHILE.

Station.	Years.	Annual evaporation, in inches.	Mean temperature, in degrees Fahrenheit.	Mean wind velocity, in miles per hour.	Remarks.
Yuma Citrus, Ariz. ....	1921-23	122.81	70.7	3.03	Station 8 miles southwest of Yuma on desert mesa.
Yuma Citrus, Ariz. ....	1921	135.70	70.7	3.03	Maximum during 3 years, 1921 to 1923.

San Pedro .....	1917 and 1918	117.15	About 50	About 10	In mountain region subject to annual precipitation of about 1.7 in.
Chuquicamata .....	Various observations, 1917-27	144.00	" 58	9.81	In arid desert, very little precipitation.
Calama .....	1917	113.40	" 57	Ranging between 6 and 8	Within irrigated area, very little precipitation.
Chacabuco .....	1917 and 1918	181.00	" 65		In arid desert, rainfall minimum, about once in 2 years.
Quilagua .....	1917	119.00	" 65		Within irrigated area, rainfall minimum, about once in 2 years.

\* From paper by Ivan E. Houk, M. Am. Soc. C. E., entitled, "Evaporation on United States Reclamation Projects," *Transactions, Am. Soc. C. E.*, Vol. 90 (June, 1927), p. 266.

The underlying rock formations are of such structure as to cause loss of much of the water passing through them. Some of the waters that wander away through limestone passages or surface sediments, are certain to return to the main channel because of the water-tight flooring of hard crystalline rocks. On the other hand where such waters have access to underlying stratified rocks of a permeable nature, heavy losses result, due to the steep slopes which facilitate subterranean flow direct to the ocean. It is difficult to trace waters lost in the pervious strata of sandstone because the overlying mantles of detritus are sometimes hundreds of feet in thickness.

Thus far, losses due to seepage have not called for considerable attention because of the moderate water requirements. With increased exploitation of the mineral resources of this region the engineer must face the task of reclaiming these waters or of preventing their escape. As far as the writer knows, no deep borings have been undertaken to reach the underground flows, which probably become concentrated within buried drainage systems of the past.

*Absorption of Salts.*—Some of the volcanic barriers through which the flows pass contain considerable salts of uncertain origin. Perhaps they were caused by decomposition of volcanic tuff due to fumarolic waters, such as still exist in the region. Again, they may be from vast beds of sodium chloride which crystallized out in basins as the continent was elevated more than two miles out of the sea, later to be covered with volcanic materials. Whatever

the cause, many of the waters that are chemically quite pure near their sources, acquire so much salt while passing through volcanic formations, particularly at the lower boundaries of the basins of sediments, that they cease to be potable.

Chemical concentrations are highest in waters of geysers and boiling springs. The geysers of the Tatio initiate a flow of 14.8 cu. ft. per sec., with a chlorine content of 4 200 parts per million. The Chilean Government once considered diverting this river to an evaporating basin outside the Rio Loa System, but a study of the economics of such an undertaking caused it to be abandoned.

Seldom are waters of the desert so chemically pure as those ordinarily used in regions of normal rainfall. Only at the upper reaches of the Loa System (Table 1) is the water low in chlorides and sulfates. In the United States, waters containing chlorine in excess of 20 parts per million are not desirable because of corrosion to boilers and plumbing fixtures. In Northern Chile chlorine tolerance for potable waters and those used for generating steam is usually set at 50 parts per million, and the Chilean Government has stretched the point slightly by including within this category waters of the Rio Loa System which have as much as 62 parts per million.

Whereas waters used in steam boilers may be treated for sulfates and carbonates, the writer knows of no practicable way of eliminating chlorine. The waters of the Rio Toconce, containing 62 parts per million of chlorine, have been used for a number of years in locomotives. The Antofagasta-Bolivia Railroad Company at one time used the water of the Rio San Pedro having 195 parts per million of chlorine, but had to obtain other supplies. For drinking, waters similar to those of the Rio San Pedro are apt to have a mild purgative effect. Those having as much as 1 000 parts per million of chlorine are not fit to drink. The people of the Village of Quillagua, although very poor, purchase drinking water from the Railroad Company at the equivalent of 1½ cents (U. S. currency) per gal., rather than use the brackish water of the Loa.

For irrigation the Chilean Government classifies as good, waters not exceeding 200 parts per million in chlorine. In general, only the Indian communities near the head-waters of the region have such water. Nevertheless, good crops of alfalfa, corn, and some vegetables are raised with water of from two to ten times this maximum.

Streams which spread out to form marshes are naturally high in salinity. The salt content of most of the waters of the region is also increased 50% or more during the summer season, when the rains in the upper sections dissolve saline efflorescences.

In the basins without outlet, the lakes have a widely diversified chemical content, including alkalis and borax. The impotability of many of these waters is attested by the bones of animals along the shores. In other lakes, as the Laguna Colorada, the brackish water forms a large pool in the center, separated by crystallizations of salts from the outside waters, which are potable.

## INTAKES FOR POTABLE WATER SUPPLY

In view of what has been said about evaporation and seepage losses as well as the acquisition of soluble salts, apparently potable water intakes might best be located at the upper sources of the feeders, that is, at the snow drainages, before they disappear into the reservoirs of sediment. This is seldom feasible, however, because of (a) the high altitude and general inaccessibility of such places; (b) the intermittent character of flow due to freezing; and (c) the fact that in very dry years there may be no flow at all.

In a few cases snow drainage water, although flowing underground, has been piped by building subterranean dams—such works being limited to narrow valleys. At others, the waters have been taken from rivers at elevations between 11 000 and 14 000 ft. Tunnels driven into sandstone formations to collect and divert ground-waters to intakes have also been resorted to, but they seldom yield as much as natural springs. For example, the fifteen canals of the Pica Region, Province of Tarapaca, discharge but little more than 1 cu. ft. per sec., despite their 8 miles of length.

An advantageous location for the intake is at the springs where the waters issue from the natural reservoirs. They may have already dissolved some salts, but not in large quantity. Small canals carry the water to the settling basin at the intake of the pipe line (Fig. 4).

Where waters are removed from streams, the diversion dam and intake chamber require merely sufficient height to keep the pipe line from drawing air. Constant cleaning is necessary, for not only is there considerable sediment, but also floating matter, chiefly pebbles of pumice, washed from the ground by the rains. Pollution by sewage seldom calls for consideration in locating a potable water intake, for the water sources are rarely inhabited.

## PIPE LINES

Pipe lines depend on gravity in the upper sections and pumping stations in the lower. The pipes are nearly always of steel or cast iron; wood-stave lines, although cheaper, are hardly safe in regions of the desert where water is scarce and scruples are few. One structure was made of hard durable metal on purpose "to resist destruction by travelers who ordinarily take such objects as targets for revolver or rifle shots."

These lines are laid on the ground with a covering of about 15 in. of soil, except at the joints. This protects them against temperature changes which sometimes amount to 80° Fahr. within 12 hours in Northern Chile. The pipe line full of water is not as a rule affected by temperature, but when a break occurs difficulties may ensue. Pipe lines are covered as they are laid, using expansion joints to take up such temperature stresses until the earth covering becomes compact.

In many cases the water is conveyed for long distances, the supply of the City of Antofagasta traveling 230 miles. Some of the lines are operated under but little pressure, open tanks being located at intervals. Others, which cross low valleys, necessitate pressures as high as 1 000 lb. per sq. in.

The design of pipe lines oftentimes presents complications. Transportation of materials must be considered in the location (Fig. 5), for, in country covered with lava flows and cut by deep canyons, delivery costs may far exceed the value of the pipe.\* Also, important is the hydraulic grade, particularly in the section just below the intake where the line must generally be located within the bounds of a deep precipitous canyon. Here, construction expenses are high. Yet to reduce them by resorting to a minimum grade for the pipe line is apt to be short-sighted, due to the tendency of the hydraulic grade to fall below the level of the pipe after several years of operation, with diminished capacity and other troubles resulting. The writer recalls one instance wherein it was necessary to lay "looping" lines after eight years of operation, in order to bring a pipe line to the minimum capacity for which it was designed.

#### OPERATION

The high chemical content of the water is apt to make pipe corrosion problems more acute in desert regions than under similar conditions in humid lands, for sulfates and chlorides, usually so abundant, aid the attack on iron. In Northern Chile, analysis of nodular incrustations found in a pipe line showed a composition of 0.8% sulfate radical and 0.2% chlorine, a concentration which is quite remarkable considering that only 50 and 62 parts per million of these radicals occurred in the water itself. Ground-waters of regions of recent volcanic activity, where rainfall is scant, are apt to contain large quantities of carbon dioxide and hydrogen sulfide, both gases being agents of corrosion. The warmth of spring waters (often as high as 75° Fahr. throughout the year) also contributes to their corrosive properties.

Because of the corrosive quality of these waters, it is highly important that air be excluded from pipe lines. When the hydraulic grade line falls below the level of the pipe, even for transient periods as when scouring is done, water wasted, or branch lines are fed, air is admitted and conditions favorable to corrosion are set up.

For removing sand and sediments, sand traps are best, as they do not cause the impairments so often attendant upon scouring. Valves for emptying a pipe line are necessary, as for discharging the water when repairs are in progress; but when such valves are to be used for scouring, their locations as well as the manner of their operation call for careful study. One company used floating balls of hollow metal for ridding its line of sand. The ball was made about 1½ in. smaller in diameter than the pipe. When its progress was checked by accumulations of sand the pressure rose and the obstruction was removed. At the same time the ball was not so large as to endanger the line by completely blocking the flow. Its passage could be checked by the noise which it made—in fact, a dog was trained to follow and bark at it.

Automatic air-release valves, located at summits where the pressure is low, serve to eject some of the air entering the line. With cold non-corrosive water, and steady flow maintained under pressures greater than atmospheric,

\* Mules had been used to a great extent in the past for haulage and distribution. In more recent years, motor trucks, tractors, and trailers have effected considerable savings over the older methods, despite the initial expenses for road building. In soft sandy portions of the desert, caterpillar trailers have been used to good advantage.

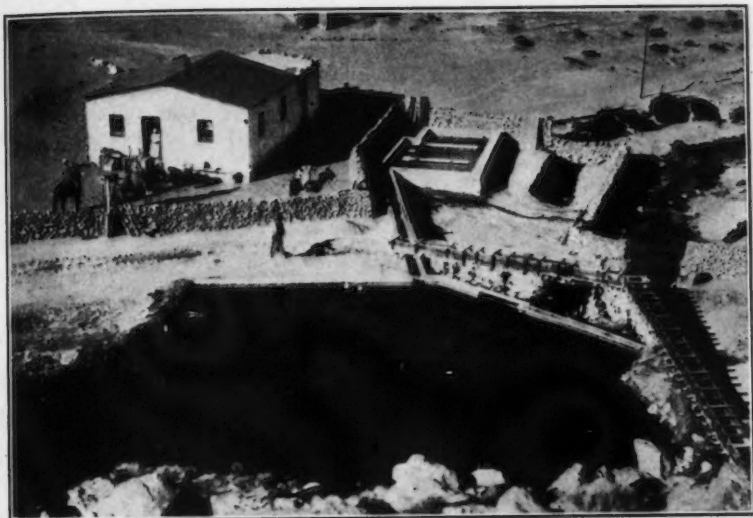

FIG. 4.—VIEW SHOWING SMALL CANAL CARRYING WATER TO SETTLING BASIN AT INTAKE OF PIPE LINE.

FIG. 5.—METHOD OF TRANSPORTING MATERIALS FOR PIPE LINES IN CHILE.

deterioration of a long-distance water main will be slow. With corrosive water, it may be well to install works for de-aerating the water or rendering it non-corrosive at the source.

Some protective coatings appear sufficiently substantial to safeguard a line against corrosion. However, until a coating is found combining low cost with durability it will probably be more economical to take measures to exclude free oxygen from pipe lines.

The type of joint is another matter which is important. Too frequently the common screw coupling provides most favorable conditions for storing air, with consequent chemical injury.

#### OTHER MEANS OF TRANSPORTATION OF WATER

Many of the villages are supplied from tank cars, the inhabitants making daily trips to the station to fill their cans. Another means of distribution is the mule cart, with its daily rounds of nitrate district villages as well as smaller pueblos. In more isolated districts, one sees mules and burros carrying potable water, often for 20 or 30 miles. Whereas 26 gal. per day per inhabitant within cities, and half that quantity outside of cities, are the quotas on which the Chilean Government bases concessions for drinking water supplies in its desert provinces, the actual use of water is generally less. This is due to the extreme poverty of the people. Large industrial companies have inaugurated the practice of furnishing free water to workmen and their families, as well as providing sanitary toilets and bath houses for their use.

#### IRRIGATION

A potent argument for conservation of water resources in desert regions under development lies in the needs of agriculture. Where food is scarce and expensive, with increments of population continually being brought in to work at mines and industries, all surplus water is required for irrigation. This applies not only to flows lost through seepage and useless evaporation, but also to those that reach the sea.

In Northern Chile large water resources are still being lost or wasted. Indian dwellers of the highlands have installed irrigation canals, marvels of ingenuity, within the canyons of the upper drainages, but these produce only sufficient for their owners' needs. Farming centers in sections of lower altitude cultivate alfalfa in quantities, but only small quantities of foodstuffs. Meanwhile, imported food fills the shelves of every store, and that from Central and Southern Chile has to be transported about 1 000 miles.

That irrigation can produce successful crops has been demonstrated at Chiu-Chiu, Calama, and Quillagua, within the Rio Loa Basin. Yet this river pours 36 cu. ft. per sec. into the sea during the farming season. Once there was a project—work had actually been begun, in fact—to enlarge the cultivated area at Quillagua. The plan came to naught when the earthquake of 1879 destroyed some of the completed canals. It can be only a question of time before foreign capital interested in the nitrates and minerals of this district will take the matter in hand.

## HYDRO-ELECTRIC POWER

In a region where water is scarce it would be thought that hydro-electric power possibilities would be of little consequence. This does not necessarily follow, for a meager supply may be balanced to some extent by the high head available.

With present low prices for fuel oil, developments of the hydro-electric resources of the Loa and adjacent basins do not appear attractive. Yet such potential installations, costing between \$450 and \$500 per h.p., require no considerable rise in fuel costs before they assume importance. A few water-power plants, generating about 500 h.p. per installation, have been in operation in the lower sections of the Rio Loa for some years, in connection with the nitrate industry.

As a source of energy, however, the harnessing of the Loa and adjacent waters has hardly been begun. Projects at the upper feeders of these rivers are unique in that they call for series of power houses using the same water again and again. The Rio Salado and its tributaries may be utilized through a head of 5 000 ft. in 35 miles above its confluence with the Loa, developing about 8 000 h.p. Discharges from springs of as little as 0.1 cu. ft. per sec., when at the higher elevations, represent important potential energy and in many cases are well worth diverting to the canals.

Storage reservoirs are seldom advantageous, due to the constancy of stream flows and to the high rate of evaporation. The diversion dam at the intake of the canal requires only sufficient height either to meet the requirements of diurnal variations, due to freezing of tributaries in the upper regions, or to regulate flow below sections when irrigation is carried on during the daylight hours, in the lower regions.

A contributing factor in making these projects so expensive is the porous nature of many of the rock formations. Lined canals are necessary for the most part, particularly in view of the scarcity of water. The volcanic rock formations of the mountain region are peculiar in that the hardest and most durable often occur at the surface, so that erosion has formed overhanging cliffs at canyons, with massive fallen fragments among the talus beneath. Needless to say, such conditions call for expensive construction to safeguard water-works.

Only above an elevation of 12 000 ft. need power-house roofs be designed for snow load. Frost does not affect foundations carried 2 ft. below ground.

Some water supply pipe lines have been designed to furnish energy for operating power plants in this region. A small emergency plant, installed near the outlet, is quite certain to justify its cost, provided the pipe line is not overstressed under the increased pressures.

## DISTILLATION OF OCEAN WATERS

Distillation of ocean waters is another source of supply. The seaport of Tocopilla obtains its water in this way, at a cost of \$0.60 (U. S. currency) per ton, and more. With a prosperous period for the Chilean nitrate industry and consequent growth of this port, a pipe line from the Cordillera region would seem necessary.

This method is out of the question for the nitrate and mining centers as these are situated at elevations of 3 000 ft., or more. A drinking supply for a large number of these establishments is obtained by distillation of brackish river waters.

#### CONCLUSION

It has been seen how the projecting of water-works in a desert region may involve a great variety of problems, from the utilization of snow waters at 3 miles above sea level to the distillation of waters of the ocean itself. So scant is the supply in the Atacama Desert of Northern Chile that, with expansion of industry, the engineer is apt to be delving within the realms of geology and chemistry in order to find ways of conserving the quantity and quality of the water available.

## DISCUSSION

LEWIS R. EAST,\* Assoc. M. Am. Soc. C. E. (by letter).—Australia has a land area of 3 000 000 sq. miles, which is slightly greater than that of the United States. It is, however, less favored in the matter of rainfall and, in consequence, is peculiarly destitute of great rivers. Fortunately, over large areas, underground water supplies, of good quality, can be obtained at reasonable depths. In the arid and semi-arid regions, considerable work has been done in providing water supplies for domestic, stock, and irrigation purposes.

Apart from comparatively short coastal streams, the only rivers of consequence are the Murray and its tributaries, which, during the winter months, have a total navigable length of approximately 3 212 miles. The Murray Basin has an area of 414 000 sq. miles, of which only 159 000 sq. miles can be regarded as contributing to the river flow, and some of this to a small degree only. Part of the catchment has a heavy rainfall, and some of the mountainous areas are covered with snow for several months in each year. The average annual rainfall over the whole area is, however, only 13 in.

Evaporation losses appear, from observations, to range up to a maximum of about 60 in. per annum. In a year of low rainfall, the total discharge of the Murray River System has fallen as low as 2 327 000 acre-ft., while in a wet year the run-off is more than twelve times this amount, the average being 9 328 000 acre-ft.

It has long been realized that storages are essential for the economic use of available supplies, and—especially in Victoria and New South Wales—all political parties for many years have followed progressive policies in regard to water conservation.

On the Murrumbidgee River, one of the tributaries of the Murray, a cyclone concrete dam 200 ft. high was completed in 1925 to impound 772 000 acre-ft. of water, and on the Upper Murray good progress is being made with the Hume Reservoir which, when completed, will store 2 000 000 acre-ft. This storage will rank with those of the Gouin, Elephant Butte, and La Boquilla Dams, among the world's largest artificial storages. On the Goulburn River and other tributaries, storages have been completed with capacities totaling 800 000 acre-ft., and other works are under construction which will bring the total storage on the Murray and its tributaries to more than 4 000 000 acre-ft. The waters thus conserved on the Murray and other smaller river systems in Victoria are being used largely for irrigation; but they will also be used for domestic and stock supplies on several millions of acres outside the irrigation areas.

The State of Victoria under the administration of the State Rivers and Water Supply Commission (corresponding to the Bureau of Reclamation, of the United States) already has made considerable progress in water supply and irrigation development. It should be remembered that one of the first irrigation plans in Australia—and certainly the earliest, involving high-lift pumping on a large scale—was inaugurated in 1887 by Mr. George Chaffey who later

\* Engr., State Rivers and Water Supply Comm., Blackburn, Victoria, Australia.

played such an important part in the development of the Imperial Valley, California.

In this discussion, the writer wishes to describe some of the problems of domestic and stock water supply in arid and semi-arid parts of Australia, and the methods by which these problems have been solved. This will be confined to a description of the various water-works supplying the northwest part of the State of Victoria, in Southeastern Australia, over which the mean annual rainfall varies from 20 in. in the more favored Wimmera Area to 12 in. in the far north, or Mallee Area.

*Geology.*—The geology of the Mallee Area has an important bearing on its water supply. In geologically recent times it was covered by a great inland bay into which discharged the head-waters of what are now the rivers of the Murray System. Later, as this bay became entirely cut off from the sea by drifting sands and marsh growths, lacustrine conditions developed, and the depression was gradually filled with sands and gravels brought down from the surrounding ranges. The whole area thus became a vast sandy plain over the margins of which the streams continued to pour their burdens of silts, sands, and gravels.

The materials laid down before and after the area was raised are entirely distinctive—the latter, or fluvialite, being gray, and the former, or lacustrine, being red. While the fluvialite deposits were gradually extending over the edges of the lacustrine area, the surface of the remainder, under semi-arid conditions, was being blown broadcast by wind action until the whole of the exposed lacustrine area had been redistributed. The Mallee country now consists of low sand ridges interspersed by harder flats, generally with an east and west tendency. The larger streams have joined to become the Murray System and have cut their way through these deposits exposing cliffs varying from 60 to 180 ft. in height. The lesser streams from the south “lose themselves” in the sands and do not reach the Murray. Many salt lakes remain in low-lying sections, but throughout the Mallee (the Victorian Area is 11 000 000 acres), there are no defined watercourses other than the Murray Canyon itself.

*Natural Water Supplies.*—As may be expected, natural surface water supplies are exceedingly scarce and unreliable in the Mallee country, which up to comparatively recent years was shown on maps as “sandy desert covered with dense scrubs of *Eucalyptus Dumosa*”. This *Eucalyptus Dumosa* is the Mallee scrub which gives its name to the area. After heavy rains, surface water can frequently be obtained where, under favorable conditions, rain water collects and lies for months in depressions or clay pans. “Soaks” can also be located by experienced observers at places where ground-water can be obtained by digging a few feet. The aborigines were adepts at this, and many native wells have been found. Mallee exploration was attended by great hardships due to lack of water. Historical records tell of one of the early surveyors who reached the river only after killing his horse and drinking its blood.

The first efforts of early settlers were naturally to develop available “soaks” and catchments. Where water collected naturally at clay pans, a hole was sunk and lined with pine logs (a native tree, *Callitris Robusta*, which is not

the true pine). This was roofed over to reduce evaporation, and it held small quantities of water for domestic use over long periods of dry weather.

*Shafts or Wells.*—In certain localities near the mountains, shafts were sunk to underground water—sometimes to depths of several hundred feet in extreme cases—and timbered. Water was raised by means of horse works, windmills, or engines.

*Catchment Tanks.*—Catchments are sometimes natural, that is, open spaces with hard ground; but generally they are prepared by clearing suitable slopes and plowing complete systems of catch-drains leading to excavated tanks which must be located in good "holding ground", that is, in clay. Catchment tanks vary in depth according to the depth of clay available, and excavation must not go through the clay to underlying porous drifts. Side slopes vary from 1 on 2 to 1 on 3, and for average depths, up to 15 ft., the cost of excavation by scoop teams is about \$0.30 (15d) per cu. yd.

It has been found that, with a 12-in. rainfall, approximately 20 acres of catchment are required for each 1 000 cu. yd. of storage (170 000 Imperial gal.). The actual percentage of run-off is very low, because a 0.5-in. catchment is rare, that is, a catchment which will run water with a 0.5-in. rain. Practically all supplies are obtained from occasional heavy thunder-storms of more than about 1 in. Trampling of the catchment by grazing stock is advantageous, but cultivation, of course, cannot be permitted. The minimum storage capacity for a wheat farm of about 1 sq. mile in area, is about 2 000 cu. yd. which requires about 40 acres of catchment. The best catchments are reserved for public tanks and the largest tank thus far constructed and filled in the Mallee has a capacity of 40 000 cu. yd. When Mallee lands are thrown open for selectors, an addition of from \$0.73 to \$0.97 (3s to 4s) per acre is made to the purchase price to pay for preliminary road and water supply works. This addition or "loading" is paid by the settlers at the same time as land installments over a period of from 20 to 40 years. The full amount of the loading is, therefore, not available immediately for works; but the present value—approximately three-fifths—is spent in constructing public catchment tanks and in grubbing roads for access to the farms.

To reduce evaporation losses which are considerable, tanks are sometimes covered by roofing with wire netting overlaid with dry grass tussocks to a depth of from 1 to 2 ft. Usually, only the edges are covered, the center being left open. This is found to be quite effective.

*Rock Catchments.*—Mention should be made of the "rock catchments" of Western Australia where outcrops of solid granite have been surrounded by cement masonry drains leading to adjoining excavated storages. There are in some parts of this State catchments of several hundreds of acres in area and 150 ft. above the general level of the surrounding country. These rock catchments yield as much as 95% of the first inch of rain and practically all of any rain following immediately.

Storages adjoining the catchments are generally excavated to a depth of about 15 ft., the bottom 10 to 12 ft. being water-tight clay, above which there may be from 3 to 5 ft. of porous material. Loss of water is prevented by

excavating a trench to clay under the site of the spoil-banks and filling this with clay pug.

**Bores.**—Below the æolian surface soils of the Mallee and red lacustrines there is a more or less impervious blue clay band under which are considerable thicknesses of marine tertiaries, containing water under artesian conditions. This water is invariably mineralized to a greater or less extent—sometimes approaching saturation—and the minerals in solution are as invariably in the proportions of sea water. There are generally several layers of water at different depths, that is, perched basins, and the top water is usually of very inferior quality. In the southwestern part of the Mallee adjoining the South Australian boundary, usable water containing about 70 parts of dissolved salts per 100 000 is obtained by boring to depths of from 100 to 200 ft. This water rises to within about 50 ft. of the surface. At greater depths of from 450 to 550 ft., water containing as little as 35 parts of dissolved solids per 100 000 has been obtained, and as much as 6 000 gal. per hour has been pumped from a bore, 6 in. in diameter, at this depth without unduly lowering the level of water in the bore. To the east of this district the depth to usable water increases and the quality of the water deteriorates until in about 60 miles a limit of about 500 parts per 100 000 is reached. Farther east the quality is even worse.

Limits of salinity (total dissolved solids) vary according to the nature and proportions of the salts in solution, but in the Victorian Mallee (sea-water proportions) may be taken as follows:

Human consumption.	Good.....	30 parts per 100 000;	0.05 oz. per gal.
	Medium..	60 " " "	; 0.10 " " "
	Bad.....	150 " " "	; 0.25 " " "
	Limit....	620 " " "	; 1.00 " " "
Working horses	Good.....	300 " " "	; 0.50 " " "
	Fair.....	400 " " "	; 0.625 " " "
	Limit....	500 " " "	; 0.80 " " "
Grazing stock	Limit....	900 " " "	; 1.50 " " "

Under inland conditions sheep have been known to do well on water containing 2 oz. to the gallon when they drank it continuously.

The area under which usable water can be obtained covers about 1 000 000 acres of agricultural lands. In this region the State Rivers and Water Supply Commission has driven nearly 100 bores, each supplying water for eight or nine farm holdings of 700 acres. The bores (mostly 5 in. in diameter) are cased so as to cut off waters of inferior quality, and, in general, are equipped with windmills 12 ft. in diameter on 30-ft. steel towers. Storage is provided by 4 000-gal., corrugated-iron tanks on timber or steel stands. The cost of a bore complete with mill and tank averages about \$1 200 (£250), the actual boring costing about \$2.43 (10s) per ft.

As the water is generally neutral or slightly alkaline, the casing has a long life; no failures due to its corrosion are known in this area although many of the bores have been operating since before 1914. The entire cost of constructing and maintaining the bores is met by rating the lands that are benefited; the actual rate averages about \$0.04 (2d) per acre per annum. The cost of maintenance and repairs is about \$100 (£20) per bore per year.

*Channels.—Gravitation Supplies.*—The bore area is limited. Catchment tanks, which completely failed in times of drought, proved inadequate to meet the demands made on them as the country developed and the urgent necessity of providing assured and ample water supplies for working and grazing stock has resulted in the development of an extraordinarily extensive system of channels bringing water from the wet south to the dry north.

As might be anticipated from its geological formation, the Wimmera-Mallee Area has a general northerly slope from the southern water-shed—the Grampians and the Dividing Range. From these ranges a number of small rivers cross the Wimmera plains and disappear in the sandy soils of the Mallee. None of them reaches the Murray or the sea, even in times of great flood. As early as 1880, the natural flow of the chief of these streams, the Wimmera River, was diverted into channels by means of timber weirs and carried to excavated tanks on farms in sections of the country where there were no defined watercourses. By 1891 about 500 miles of these channels had been constructed. The only storage at this time was Wartook Reservoir of 24 000 acre-ft. capacity. A further storage (Lake Lonsdale, 45 000 acre-ft.) was completed in 1902 at the end of a drought year in which the whole distribution system practically failed. After the constitution of the State Rivers and Water Supply Commission in 1906, all these works came under Government control and considerable extensions were made.

The old method of using creeks and watercourses as main channels resulted in excessive evaporation and seepage losses. The Commission, therefore, abandoned all natural depressions and laid out a system of main channels suitably located along main ridges to command practically the whole of the Wimmera and Mallee Districts. Water from storages has been taken across rivers by means of low-level weirs or diversion dams which not only enables it to cross the streams, but also permits any river flow available to be diverted into the main channel. In normal seasons the river flow is sufficient to keep the main channel full throughout the winter and spring without drawing on the storages which are thus kept in reserve to make up deficiencies during periods of little or no flow.

Since 1906 the area served by the Wimmera-Mallee Gravitation System, has been more than trebled until at present (1929) about 11 000 sq. miles are supplied from its channels. To serve this area, which includes 35 townships and has a population of 100 000, more than 5 100 miles of channels have been constructed by the Commission. The longest Government channel carries water a distance of 300 miles from the storages in the hills into the far north. This great extension of the original plan has necessitated full development of the catchments of all streams supplying the area and the total capacity of storages is now 200 000 acre-ft. Slightly less than one-half of this is required for watering the whole area in an average year.

The channels vary in capacity from 700 to 4 cu. ft. per sec., and their grades also vary from 10 ft. per mile to 9 in., depending on the fall of the country and the size of the channels. The velocity of flow is usually kept about 0.5 ft. per sec. Channels in cuts as deep as 4 ft. have side slopes

of 1 on 1, and for greater depths, 1 on 1.5. In very sandy land, such as that in desert country, the channels are lined with about 1 ft. of clay or loam to minimize seepage losses, but in general they are merely excavated in the earth. In designing channels for domestic and stock water supplies, it is usual to allow 1 cu. ft. per sec. for every 40 sq. miles, but no main channel should be designed for less than 10 cu. ft. per sec. and the smallest distributary (bed width usually 3 ft. for reasons of construction), should be not less than 4 cu. ft. per sec. The extreme length of a small channel of this size should not exceed 10 to 15 miles. For longer channels the capacities must be increased, regardless of the actual area served.

It must be remembered that no irrigation is permitted from the channels of this system; all the water available is required to run the channels, in which seepage and evaporation losses are very great, and to fill excavated storages on each farm once per year, with enough water to serve all needs for the full twelve months until the next run of the channels. As far as possible the channels are run during the winter months in order to reduce seepage and evaporation losses. Farmers are required to provide tanks on their holdings of a total capacity equivalent approximately to 4 cu. yd. for each acre; that is, 2 500 cu. yd. for a 640-acre holding. The minimum depth required is 12 ft. and, as channels are generally on high ground, storage above ground level is frequently possible. Excavation is, therefore, often only two-thirds of the full capacity, the remainder being carried above ground level by banks. The minimum supply necessary for an average farm of about 640 acres is about 750 cu. yd., or 120 000 Imperial gal. per year. This will suffice for about 200 sheep, 6 cattle, 12 horses, and 10 persons. An open storage of 2 500 cu. yd., or 425 000 Imperial gal., will yield this quantity after allowing for all evaporation losses and waste during the year.

As in the bore areas, the landholders are rated on a valuation basis to cover the cost of the project. The average rate is from \$58 to \$100 (£12 to £20) per sq. mile, with a minimum of about \$52 (£10/13/4) per sq. mile, or \$0.08 (4d) per acre. The charge is not based on the quantity of water supplied. To encourage the landholders to put down storages of ample capacity the Commission charges no more for filling a 15 000-cu. yd. tank than one of 2 500 cu. yd. Under favorable conditions 200 miles of channel can be run in 30 days, but in more porous country the time required might be 60 days.

Maintenance consists largely in removing sand-drift blown into channels during hot windy weather. In the parts of the Mallee particularly liable to "drift", channels are occasionally entirely filled with sand blown by one storm. Thirty-five townships within the area commanded by the Wimmera-Mallee System have pipe reticulatations supplied from local storages which are filled annually from its channels.

The project has cost \$8 750 000 (£1 800 000) to date, or a little more than \$100 per acre, and is proving a sound financial proposition to the State apart from its general contribution to the prosperity of the country.

*Channels.—Pumped Supplies.*—In addition to this great gravitation system the Commission has completed several independent projects by which large areas are supplied with water for domestic and stock purposes through channels filled by pumping from the River Murray. In the County of Millewa approximately 1 000 sq. miles are thus supplied through separate low-level and high-level channel systems. Three pumping plants are required to serve the lower system, which is approximately 145 ft. above river level. The main lift is 103 ft., and the minor lifts, 13 ft. and 19 ft., respectively. The high-level system requires a further lift of 135 ft., thus raising the water a total of 270 ft.

For the low-level system (known as the Lower Millewa Water-Works District), the average rate is \$0.16 (8d) per acre, or \$103 (£21/6/8) per sq. mile. For the high-level (or Upper Millewa District), the rate is \$0.20 (10d) per acre, or \$129 (£26/13/4) per sq. mile. The length of public channels constructed in the Millewa Districts to date is approximately 700 miles.

*Pipe Reticulation.*—In the State of Victoria the supply of water to farms through pipe reticulations has not been extensively adopted owing to its great cost. However, in the adjoining State of South Australia, several such layouts have been in operation for a number of years and one, the Tod River Water Scheme,\* when completed, will have in its 240-mile main one of the longest pipe lines in the world, second only to the 350-mile Kalgoorlie Goldfields Main in Western Australia.

The Tod River Water Scheme is designed to supply water to 10 000 sq. miles of agricultural land through a 240-mile main and 1 000 miles of distributaries. Water from the Tod River and its tributaries is diverted into a reservoir of approximately 10 000 acre-ft. capacity and thence pumped through 2½ miles of 18-in. rising main to a small concrete-lined reservoir on Knotts Hill, holding 20 acre-ft. From this reservoir the whole area is commanded by gravitation. The main varies from 20 to 10 in. and is of steel—the last 110 miles being concrete-lined. A break-pressure basin, also of 20 acre-ft. capacity, is provided at about 128 miles from the beginning of the main and 259 ft. below the full supply level of the Knotts Hill Reservoir. Rating is based on the unimproved valuation and varies from \$0.08 (4d) to \$0.14 (7d) per acre on all land within 1 mile of a main. The estimated consumption of water, based on actual figures in other areas is 132 gal. per acre, or 84 480 gal. (Imperial) per sq. mile. For the rate, 43 000 gal. are allowed and the excess is charged for at \$0.49 (2s) per 1 000 gal. The total cost of the work will be approximately \$14 100 000 (£3 000 000), or \$6.00 (25s) per acre, but there is little prospect of the system paying more than operating expenses. The annual deficiency to be met by the State will be about \$730 000 (£150 000), with no provision for depreciation. The work has greatly assisted in the development of the district and is, therefore, probably justified by its addition to the revenue and prosperity of the State.

\* *The Engineer*, August 10, 1928, Vol. CXLVI, p. 149.

The Kalgoorlie Goldfields Water Supply Project\* (Western Australia) comprises a very bold and ambitious plan for supplying 5 000 000 Imperial gal. of water per day to the inland goldfields from the coastal ranges across more than 300 miles of arid and semi-arid country.

From the Mundaring Reservoir (capacity, 4 600 000 000 gal., or 18 400 acre-ft.), a series of eight pumping stations, at intervals, force the water through a 30-in. steel pipe line over a distance of 351.5 miles and deliver it at a level 1 290 ft. above the reservoir. The works were completed in 1903 at a cost of \$16 000 000 (£3 250 000).

Since the decline of the demand for water for gold-mining purposes, a new and increasing demand has arisen for domestic and stock supplies to the splendid wheat lands adjoining the pipe line the development of which has been held up for lack of water. Not only does this demand absorb all the water thus made available but, in order to provide supplies for further areas, extensions to the system are now being considered.

*Artificial Catchments.*—The conservation of rain falling on roofs is as old as roofs themselves, but it is believed that the construction of large "roofs" on the ground—designed to catch the full water requirements of large farms—is quite novel.

There are parts of the Mallee country that are quite suitable for wheat growing, except that the ordinary channel system of water supply cannot be economically extended to them on account of the excessive cost of pumping, or of lining the channels. This is due to the porous nature of the soil, the absence of holding ground for the farmers' storages, or a combination of these factors. An experiment is being made to form a water supply of artificial catchments by laying sheets of thin galvanized iron directly on the ground discharging into water-tight covered storages.†

Taking the square mile, or 640 acres, as the unit for comparison: It may be assumed that a supply of water is needed for 6 persons, 10 horses, 2 cows, and 150 sheep. The daily consumption at maximum periods is established at 5 Imperial gal. per person, 25 gal. per horse, 8 gal. per cow, and 1½ gal. per sheep. Their requirements for a period of twelve months may be set down as 90 000 gal. net, or a little more than 500 cu. yd., the consumption being distributed throughout the year as shown in Table 3.

Examination of the available rainfall returns which cover a period of 50 years shows that 26 000 sq. ft. of a perfect catchment will provide the required volume in the worst period on record during that time, and naturally will yield considerably more in the great majority of years. Since the rainfall is not well distributed during the critical periods, a storage capacity of almost two-thirds of the minimum annual requirements is needed.

Experience has indicated that galvanized sheet iron has a considerable life in contact with the soil of the Mallee. Of the 26 000 sq. ft. of catchment, it is anticipated that the roof of the house and sheds will provide about 2 500 sq. ft. The storage tank itself, the volume of which has been fixed at 65 000

\* *Minutes of Proceedings*, Inst. C. E., Vol. CLXII and CCV.

† The method known locally as the "Ironclad Catchment" has been developed by Mr. A. S. Kenyon, an Engineer of the Victorian State Rivers and Water Supply Comm.

gal. to provide a safety margin, will have a roof area of 2 100 sq. ft., leaving 21 400 sq. ft. for the ironclad ground catchment. The tank is lined with cement concrete, 3 in. in thickness, coated with bitumen. An overflow channel leads surplus water away to prevent erosion. The tank is roofed with galvanized corrugated iron, 26 gauge, closely sealed all around and supported on 4 by 1½-in. steel joists spanning the tank. An ordinary hand pump is fitted to the tank, which, together with the catchment, is fenced in with a stock-proof fence. If separate storage, about 7 000 gal., is provided at the house and sheds, the catchment tank may be reduced to 58 500 gal.

TABLE 3.—ESTIMATED WATER REQUIREMENTS FOR 6 PERSONS, 10 HORSES, 2 COWS, AND 150 SHEEP.

Month.	Gallons (Imperial).	Gallons per day.	Rainfall required on 26 000 sq. ft. (Pouls).
January.....	15 000	500	111
February.....	13 000	460	96
March.....	10 000	330	74
April.....	9 000	300	67
May.....	6 000	200	45
June.....	3 000	100	23
July.....	3 000	100	23
August.....	2 500	80	19
September.....	3 500	120	26
October.....	4 000	130	30
November.....	9 000	300	67
December.....	12 000	400	89
Total for year.....	90 000	250 (daily average)	670

To date (1929), only experimental public catchments have been constructed. For actual farm allotments it is proposed that the Commission supply the iron, cement, timber, and pump; pay the rail freight; land the bending and punching machines, and line and roof the storage tank. The settler is to cart all material to the site; prepare the catchment surface to receive the iron; bend and punch the iron; excavate for the storage tank, about 400 cu. yd.; cart the gravel from the railway (24 cu. yd.); and fence in the catchment and tank. If it is done in this manner the estimated cost is:

Catchment iron, 8 tons, and freight.....	\$1 178
Lining concrete tank 3 in. thick and coating twice with Colas, 284 sq. yd.....	486
Corrugated galvanized iron for roof, 1 ton.....	146
Roof framing .....	97
Fixing roof, pump, etc.....	73
Anchor timber nails, etc.....	49
Contingencies .....	306

Total.....\$2 335 (£480)

This amount will be repaid by the settler in installments, together with his land purchase price. The settler will have the full responsibility for the

management and maintenance of the catchment and tank, and no annual charge for that purpose will have to be met. He may, with profit, add both to the catchment and to the storage, as his circumstances permit.

WILLIAM E. RUDOLPH,\* M. Am. Soc. C. E. (by letter).—Some notes have been contributed by Mr. East on the conservation and transportation of water for cultivation and stock-raising in the State of Victoria, Australia. These are particularly interesting because more than one-half the superficial area of Australia is arid, or semi-arid, a greater proportion than for any of the other continents.

It would appear from Mr. East's discussion that even the arid section of Northwestern Victoria (the Mallee Area) has far more rainfall than Northern Chile (three hundred times as much as in the nitrate pampa of the Atacama Desert). Evaporation is considerably less, ranging from one-half to one-third as great. Considering the scarcity of water, it follows that the costs of irrigation projects in Northern Chile would be much greater than those of the works mentioned as having been constructed in Northwestern Victoria during the past fifty years. These costs, in the writer's opinion, would be not less than \$100 per acre developed—about one hundred times as much as the Wimmera-Mallee System described by Mr. East. Nevertheless, with the favorable progress now being made in the Chilean nitrate and copper industries located in the Atacama Desert, plans for making this region self-supporting are being widely discussed. The Chilean Government, in particular, has been seriously contemplating the fact that less than 10% of the country's area is productive, and according to a recent news note† it has allocated more than £4 000 000 for irrigation projects. One-half this sum is said to be intended for the construction of dams and canals to make use of the water of rivers in Northern Chile which at present are lost in the sands of the desert.

Paper No. 1740

### LETTING CONSTRUCTION WORK BY COMPETITIVE BIDDING\*

By EDWARD W. BUSH,† M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. L. C. WASON, CHARLES J. BENNETT, CHARLES F. CHASE, WILLIAM E. RUDOLPH, LAZARUS WHITE, A. E. WALDRON, A. JORDAN BERNSTEIN, ERNEST NICHOLSON, ARTHUR W. CONSOER, F. H. STEPHENSON, JOHN C. WAIT, EDWARD W. STEARNS, RICHARD S. KIRBY, J. E. ROOT, SPENCER A. SNOOK, J. A. LENECEK, JACOB S. LANGTHORN, AND EDWARD W. BUSH.

#### SYNOPSIS

This paper is an economic study of some of the successive steps taken in the preparation for, and the actual letting of, construction work by the method of competitive bidding. The parts or elements considered are:

- A.—Preparation of the Contract, Specifications, Drawings, and Bond.
- B.—Advertisement for Bidders.
- C.—Information for Bidders, Questionnaires.
- D.—Bidding Security.
- E.—Awarding the Contract.

The endeavor is made to outline briefly a set of principles which, if followed, will assist in giving the owner the maximum value for the money expended in construction work and, at the same time, leave a profit for the contractor commensurate with the ability exercised in the performance of the contract and with the risk assumed in being bound to produce the work for the contract price. The owner supplies the funds, without which no construction work would be performed, and the contractor and his surety carry the

inherent risks of the construction operations; it is uneconomical and against the best interests of all those engaged in the industry if any of these parties, or the engineer or architect, seeks to deny or withhold from any of the other parties the full value, protection, or profit that should rightfully accrue for his part in the undertaking. The owner, the contractor, the surety, and the engineer or architect are component parts more or less leaning for support on all the others. There is need of better harmony of effort. Perhaps this paper will lead to a better understanding among these parties.

# INTRODUCTORY

In general, the paper supplements matter which has received the attention of many members in recent years.\* Since 1917 the writer has reviewed a large number of contract documents, advertisements, bidding instructions, etc., on all kinds of construction work in all parts of the United States, and has been strongly impressed with the great diversity of methods in vogue on matters concerning which any group of engineers or architects should reach practically the same conclusions. Many of these procedures might affect the contract price to an amount of, say, 5 to 25%, or even more.

To illustrate: An engineer received bids on many millions of dollars worth of public work without even drafting a form of contract. The specifications and drawings were very sketchy, and the work was let to a company that tendered an informal bid on a new process which had never been tried on work of this size and character, and on which bids had not been requested. In reality, the contract was let without competition and all the formal bidders had their trouble for naught. The high character of the engineer precludes any collusion; but it was a queer way to expend the public's money.

In many cases the engineer and the owner word the contract so that the contractor becomes financier as well, because he must accept bonds or warrants at par in lieu of cash. Naturally, he must conclude a binding agreement with some strong financial party for the discount of the paper before he can prepare his bid. The owner may think he is borrowing the money at a nominal interest rate, whereas he may actually be paying a very much higher rate, but nobody but the contractor, his banker, and his surety knows it. Another variation of this is compelling the contractor to accept the unsold portion of securities issued to finance private construction. By this vicious practice many a contractor has been forced into bankruptcy as the market for the securities is saturated before he gets his securities and he cannot raise the funds needed to meet his expenses.

A certain architect prepares his contract, specifications, and drawings so that the bidders know exactly the amount and kind of work and materials

\* The Society's Special Committees on Construction Contracts and on Engineering Contract Bonding have been engaged jointly with others in drafting the "Standard Contract for Engineering Construction," and the "Standard Questionnaires" used to determine the responsibility of a contractor, *Proceedings*, Am. Soc. C. E., March, 1926, Society Affairs, pp. 223 and 259, respectively; also, some of the members assisted the "Interdepartmental Board of Contracts and Adjustments," U. S. Bureau of the Budget, in preparing the standard contract forms now used by the United States Government; Frank T. Sheets, M. Am. Soc. C. E., has presented a paper on "Qualifications of Contractors on Public Works," *Proceedings*, Am. Soc. C. E., April 1928, Papers and Discussions, p. 1021; and Ward P. Christie, Assoc. M. Am. Soc. C. E., a paper entitled "General Contract System versus Segregated Contracts," see p. 98 of this volume of *Transactions*.

required, hence the bids are always low and close. He gets the most for the owner's dollar. Another architect, doing the same class of public work, is known to furnish incomplete drawings and specifications and may change one without the other. They leave much to the imagination, hence bids vary greatly. Contractors who have done work under him are seldom the low bidders on new work. One such experienced contractor was the second bidder on a \$1 500 000 job and \$30 000 above the low bidder. The latter got the contract and collected more than \$100 000 "extras" at completion. At times, it is doubtful whether this architect spends the owner's money economically.

#### A.—PREPARATION OF THE CONTRACT, SPECIFICATIONS, DRAWINGS, AND BOND

Many contract forms give eloquent testimony to the fact that their authors never analyzed them. Inconsistencies abound largely because the same subject-matter is treated in several places. Many contracts are too verbose. Frequently, similar matter is given in the instructions to bidders, the contract, and the specifications. To express the same thought twice in the same language is useless repetition and to express it in different languages is to run the risk of confusion. Therefore, the following principle is evident:

##### (1) Treat any subject in only one place in the contract documents.

Nobody can see very far under water, or into the earth. As the owner may change his mind after the contract is signed, every contract should be drawn with the idea that several changes will probably be made. Changes lead to claims for extras; hence the document should be worded so that any change is immediately recognized by each party, and an understanding regarding it reached. Even after the contract has been signed, the parties remain "free agents" to set up a supplemental contract and thus many claims for extras are pressed. If a contractor presents a claim months after the work has been performed, submitting a mass of records favorable to his position, the owner and his engineer are at a disadvantage because they, not knowing of the claim, have failed to gather evidence on the case.

In one contract form used on a large volume of public work there are no clear-cut distinctions between (a) increase in quantities to be paid for at bid prices; (b) "cost-plus" work; and (c) additional work at a price to be agreed between the engineer and contractor. Probably the unwillingness of contractors to start trouble with those who can give them subsequent work, plus the fair-minded interpretations of the engineers, explain why trouble has not caused this form to be clarified. Hence, the principle:

##### (2) Recognize that changes are inevitable; provide a means for promptly coming to an agreement regarding them; and require that an "extra" must be promptly declared.

Whenever doubt exists as to the exact volume, kind of work, and materials, the contractor is apt to estimate the most expensive method or amount. He cannot afford to do otherwise. Any uncertainty in the contract leads to either a higher bid than is economic or to a claim for extras, depending on whether the contractor is called on to produce at a cost less or more than he figured on.

The phrase, "as directed by the engineer (or architect)", has cost owners a pretty penny in the past. A well thought out and detailed plan always indicates to the capable contractor that the engineer is competent and one with whom there is but little chance for disagreements. The next principle naturally follows:

- (3) Every time an uncertainty is removed the price is lowered.

Many contractors are fully competent to supply an expert knowledge on certain construction matters far beyond the ordinary working knowledge of the engineer or architect. Often the results desired are specified instead of the sizes, methods, and materials; but it is unfair to hold the contractor responsible for both. To do so is to make him and his surety guarantee that the engineer or architect knows his business. The best current practice tends to be specific. This gives the contractor a more exact job to estimate, also places all bidders on an even competitive basis. Therefore:

- (4) If possible, specify workmanship and materials instead of results, but never both.

Reasonable tests or guaranties that the owner is getting the results desired are proper when results are specified, but unfair if workmanship and materials are delineated. If the owner decides to use a special process or product, let him accept the guaranty of those promoting it instead of compelling the contractor to assume the responsibility as is so often done. Maintenance guaranties on roads and pavements are manifestly unfair, because, assuming the workmanship and materials are all that they should be, no one can estimate correctly the volume and kind of traffic the road must carry later. After the contractor has completed the work in accordance with the terms of the contract his responsibility should end. Guaranties that run for a term of years increase the price and decrease the number of bidders as contractors do not wish to carry an open liability. Accordingly:

- (5) In general, do not require guaranties from contractors where workmanship and materials are specified. If required where results are specified, limit the guaranty to those things directly under the control of the contractor.

Why ask the contractor to assume a risk that might better be taken by the owner? The financing of contracts, the rental of a suitable operating space, the depth of foundations that may be required, and many other matters affect the bid price. The engineer may have several months to study the proposed construction, whereas the contractor has only a relatively short time to decide what effect, if any, these things will have on the cost. In many cases, it will pay the owner to remove some of these uncertainties in advance of receiving bids. Therefore:

- (6) It is uneconomical to hire a contractor to carry a risk which the owner can carry at a less cost.

Most State lien laws compel the owner to meet unpaid labor and material bills if the contractor is unable or unwilling to do so. A sub-contractor's bill falls in this same class. These lien laws vary among the several States. Many are grossly unfair and against the best interests of the construction

industry, and hence a joint conference has been drafting a uniform statute. Lien laws are not enforceable against a State or the Government, so it has been the custom to give Government contractors the same protection they would obtain in private work, by inserting a clause that they shall pay these bills and also by stating in the bond that the surety is liable. Labor really does not need protection because it will not work unless payrolls are promptly met, and whether it is desirable to guarantee the bills of those supplying materials is open to question. This certainly makes it easy for the irresponsible contractor to buy materials and place sub-contracts.

In all States except one or two, contractors have the full right to take money paid on one contract to retire indebtedness incurred on another, to play the stock market, or otherwise to expend it—and some of them do so. In the few States which word the contract and bond liability so that the surety is not liable for unpaid labor and material bills, the cost of a contract bond is only about two-thirds of what it is in the States where the liability is covered by the bond, because the unpaid bills generally represent a considerable part of the loss assumed by a surety when a default occurs. Hence:

- (7) On State and Government contracts, removing the surety's liability for unpaid labor and material bills, will undoubtedly lead to a reduction in the premium charge for bonds.

Plant or equipment (the words are used interchangeably) is something needed by the contractor for construction but not left in the completed structure. Usually it does not wear out on one job and frequently its cost when starting a new kind of work will equal a considerable percentage of the entire contract price. There is no reason why a public works commission should be more interested in seeing that the seller of the plant receives his pay than the seller of a piano, automobile, or anything else purchased by the contractor. Still, a form used in many important public contracts provides that the contractor must pay all equipment bills and that otherwise the surety is liable. In fact, many forms go so far as to state that if the contractor does not pay these bills the owner will do so and charge the expenditure as a payment on the contract. Thus, nothing may prevent the irresponsible bidder from getting all his bills for labor, material, and plant guaranteed. He trusts to luck that he will make a profit, but cannot lose much because he is not worth much. The best way is:

- (8) Remove all protection to sellers of equipment, as this gives irresponsible contractors an unfair credit.

In many contract forms the drawings cannot be listed or identified, and many drawings lack a date and title which ties them to a specific contract. An individual, a co-partnership, and a corporation each must sign a contract in a different way, but many forms do not recognize this fact nor attempt to record the status of the party signing. Sometimes the contract price does not appear in the contract, but a reference is made to a bid having been tendered. Frequently, no mention is made as to which alternate bid is accepted. This lax way of letting construction work is not limited to that handled by inexperienced engineers and architects as much of it comes from

supervising officers who know, or who should know, a better way. An engineer fails to discharge his full professional obligation, unless he sees that the contract form and drawings will cause his client, the owner, no embarrassment if a suit is brought. Hence:

(9) Prepare each contract with the idea that it may go into Court.

By a clause in most contracts, the contractor and his surety guarantee to save the owner harmless from all claims arising from the construction operations, patent infringements, etc. Many of these clauses are decidedly unfair because they try to make the contractor responsible for patent infringements on methods or material specified by the owner as well as on those for which the contractor himself is responsible. This leads to the principle:

(10) Do not word the "save the owner harmless" and "patent" clauses so broadly that the contractor must assume risks beyond his control.

There is a decided advantage in binding together the contract, general conditions, specifications, reduced scale copies of the drawings, bond form, etc., as many persons are properly interested in every construction work of any size, and should have the privilege of receiving the full information. Material men and sub-contractors should be bound to the main contractor with all the obligations that bind him to the owner; the terms of payment may affect the price bid by a sub-contractor; and the surety is interested in learning the exact conditions of all parts of the contract, specifications, and bond before agreeing to assume the suretyship. The best way is to give all of them the contract documents bound together; when separated, there is always the risk of submitting only a part of the proposition.

It is difficult to hold a sub-contractor or material man when he has made a losing contract, and he is apt to claim the contract voided if the method of making payments deviates in the slightest from what he had in mind when the agreement was set up. Details regarding the payments generally appear in the general conditions and these should always be attached to the specifications when copies of the latter are given out. Contractors experience grave financial difficulties at times because of having to pay 100% to material men while receiving only a partial payment from the owner covering the same items, and all because the material men bid on the specifications only, instead of the complete contract documents. It is not sufficient to state in the specifications that a certain standard form of contract and general conditions will be used, as it is always possible to insert a typed page in such a form; also, all such forms have places wherein written entries will be made. Therefore:

(11) It is desirable to bind in one document the contract, general conditions, specifications, and bond form, also small-scale drawings.

Constructions supervised by engineers are in general partly paid for monthly by unit prices applied after measuring the actual work performed during the preceding month. Constructions supervised by architects are generally paid for on a lump-sum basis and, as no accurate unit quantities have been computed, the matter of monthly payments is not so easily determined. Often the contractor submits a monthly statement of expenditures for work and materials which when approved by the architect becomes the basis for

payment. This method works well if the contractor is making a profit, but if a loss will occur it may lead to the over-payment of the contractor, and the owner may be holding as retained percentage his own money instead of funds already earned by the contractor. A much better practice is to have the contractor as soon as the contract is signed submit a schedule of all the component parts of the work with prices attached, the total of which will equal the lump-sum contract price. Thus:

- (12) On all lump-sum contracts a quantity survey, with adequate prices attached, is needed to assure the correct computation of the partial payments.

The "retained percentage" is a fund earned by the contractor but withheld by the owner as a safeguard in case of default. For many years the established practice has been to keep back a certain percentage, say, 10%, of each amount earned. During recent years some contract forms are worded so that the percentage is only withheld from payments on the first half of the work. In such cases, just before completion the owner would hold about 5% of the total contract price as against about 10% under the older method. As a matter of fact, creditors push a contractor harder near the end of a large job (perhaps realizing that a loss is imminent) than during the earlier stages of the work when the contractor may be optimistic regarding a profit.

A bank that extends a large credit early in the operations will insist that the indebtedness be reduced as the work progresses and will compel the contractor to return a considerable amount from the monthly payments, or to assign payments. The bank is in a position to make a good guess as to conditions near the end of a contract and will always turn this knowledge to its own advantage. Most contractors on large work must make a considerable initial investment when starting a job before the payments are sufficient to carry the work, so the owner runs less risk in making liberal payments at the start than near the end of a job. During the time an existing contract is nearing completion a contractor may be just starting a new job, and this is another reason why the owner needs to retain the full percentage near the end of the work. To sum up,

- (13) More defaults occur near the end than near the beginning of a contract, therefore the owner needs to retain a greater reserve near the end than near the beginning of the work.

Any reputable surety company desires to be kept fully advised on the progress of the work covered by its contract bond. At times, it can exert a considerable influence on the contractor to keep him moving along to completion, and it will refuse to bond him on new work if the old work is going badly. It would serve the best interests of all concerned if the engineer or architect would promptly notify the home office of the surety of unsatisfactory progress or pending default. A good lawyer will always advise the owner to do so in the face of trouble, irrespective of any thing in the contract that indicates such a notice is not required. Especially is it desirable to obtain the surety's consent to any change in the method of payment or to any assignment of interest. Often it is difficult for the surety to obtain accurate information as to progress and this would be obviated if the engineer or architect

would send to the Home Office of the surety a carbon copy of each monthly and final estimate. That is:

- (14) Send to the home office of the surety a copy of each monthly estimate; also obtain from the surety its consent to any important change in the contract.

In most contract forms the authors fail to recognize that the "limits" of many kinds of insurance are just as important as the insurance itself. If a person using the streets is injured by an employee of a contractor very heavy damages might be recovered; also, the owner may be named as co-defendant with the contractor if a suit is started. Judgments for personal injuries are becoming larger and larger each year and the owner may need the protection of a policy having "limits" of \$30 000 and \$60 000, whereas the "limits" of the policy actually obtained may only be the minimum \$5 000 and \$10 000. Therefore:

- (15) Carefully determine the limits as well as the kinds of insurance protection needed by the owner and contractor.

An engineer may have several months in which to prepare a job for competitive bidding, whereas the bidders have a comparatively short time in which to become familiar with the terms and details of the proposed work. The bidder adds nothing for contingency on an obscure point if there is none. On unit price contracts it is desirable to take up each item or classification and tell all about it; thus, the entire job is analyzed for the contractor and in such a way that he can price each item with the minimum effort. With this method the customary clause should be included stating that the contractor is obligated to produce a complete structure; and that the costs of parts, general expenses, etc., not specifically enumerated in the unit items, will be borne by the contractor and are to be included in the prices bid on the regular contract items. The method will also prevent disputes on wrong classification during the construction period. Hence:

- (16) On unit price contracts separately consider each bid item in sequence, telling where it is found, the amount at each place, with complete details.

If the drawings are not clear, the bidder cannot make a close estimate; also, there is a greater chance for disputes. In many cases more and better drawings will lead to lower bids. Isometric perspectives will often add considerably to the ease with which the entire project is assimilated by the bidder, and by the superintendent who later builds it. In other words,

- (17) A little extra effort on the drawings is generally worth more than the cost.

The simplest form of bond is that guaranteeing the completion of the work in accordance with the terms of the contract, also saving the owner harmless against liens, claims, loss, or damage due to causes within the control of the contractor. This will give the owner all the protection he needs. The surety companies, however, seldom draft the bonds and frequently a form is presented that greatly increases the hazards of suretyship. Some forms double the premium charge without adding any benefit to the

owner. The surety company always wants to know the exact wording of the bond before agreeing to assume the suretyship, and it is in the interests of conservative underwriting that the sureties should obtain this information. One standard form of contract states that the bond required will be "in such form as the owner may prescribe" and the surety is left in ignorance of what will later be presented. Through ignorance a "forfeiture" bond might be drafted where a simple bond form was intended.

A certain extensively used bond form states that the contractor shall "satisfy all claims and demands incurred for the same". If these words were followed by the phrase "for which the owner may be held liable", the liability would be understandable; or if this extension of liability were worded instead "and pay all bills for labor and materials used on the work", a definite suretyship liability would be created. It is doubtful whether the person who drafted this form really had a clear idea of what he was doing. The bond is really paid for by the owner and it should be drawn so that he receives full protection and no one else. For many years a certain State has saved just one-half on its premium charges merely by adopting the proper bond form. The best practice, therefore, is to:

- (18) Include the bond form with the papers given to the prospective bidder, and word it so that only the owner who pays for it will receive the protection bought.

The introductory part of many contract forms defines words like "guaranty", "surety bond", etc., and elsewhere in the contract are clauses describing the obligation of suretyship. The bond form itself generally describes this obligation. In reviewing a large number of contract documents the writer has noted, almost without exception, that the different descriptions of the obligation always disagree. From time immemorial bonds have been worded in a peculiar negative manner, and this language is not the kind that is readily inserted in a contract. Hence:

- (19) The place to delineate the obligation of suretyship is in the bond and not in the contract.

While some financially strong contractors are able to obtain a fair volume of work without competition and at attractive prices (all contractors hope some day to be in this class), most work is contracted after competitive bidding has brought the price down. The plan works best when a surety bond is taken for the owner's protection. This is generally required when public money is spent, and the volume of bond protection on private work is constantly increasing.

When a surety issues a contract bond for a contractor it extends a credit to him because it increases his financial strength for the benefit of the owner in relation to the work bonded by an amount equal to the penal sum of the bond. A contract bond does not guarantee the owner that the contractor is responsible although many of the criticisms aimed at the sureties in recent years have assumed this. The obligation of suretyship is fully discharged by a monetary payment made to the owner after he has suffered a loss caused by the contractor failing to discharge his contractual obligations. It is neces-

sary, however, for the surety to determine the contractor's responsibility for its own protection before assuming the contract bond obligation. Failing to do this, the surety will suffer the inevitable losses that go with careless underwriting. Others may form an opinion on the responsibility of a contractor, but they do not back the opinion for the benefit of the owner as does the surety company when it writes a contract bond.

Many times during recent years the surety companies have been told that they should render an inspection service along with the bond protection so that the owner will receive the surety's guarantee that the work is being performed strictly in accordance with the plans and specifications. This would trespass on the professional services of the engineer or architect and is not a function of suretyship. It is an unworkable scheme.

Surety companies are constantly dealing with claim cases and their investigations generally disclose the causes of failures. Strange as it may seem, the inexperience of the contractor and the inadequacy of the contract price, while important elements, are not the principal causes of defaults, as the sureties pay many of their largest losses on contractors who are experienced and apparently were very well qualified when the bonds were written. Over-extension, or taking on more work than is warranted by the contractor's organization, plant, and financial strength, is probably the greatest single cause of failure. Many contractors plunge on real estate and otherwise tie up their capital in speculative investments where it will not work for them when needed to turn a financial corner. The defaults of important subcontractors or failure to get labor and materials for the prices estimated, have caused many contractors to fail. It has even been stated by some contractors that the high cost of educating young engineers and architects in the technique of construction work has kept many from their estimated profits. There are many ways in which a contractor becomes irresponsible after the contract is signed, and, realizing this, the surety companies when re-letting defaulted contracts almost invariably require for their protection contract bonds executed by other sureties. They know the protection is worth more than the cost of the bond. It is a fact, that:

- (20) The owner will generally receive the maximum value for his expenditure by letting work after fair competition and requiring a contract bond for his protection.

#### B.—ADVERTISEMENT FOR BIDDERS

The purpose of the advertisement is to attract bidders. Therefore, it should be worded so as to show the prospective bidder whether or not he should spend the time and money necessary to investigate the project. A glance at the advertisements in any technical publication will prove that many of them fail to meet this requirement. A contractor will probably make a lower bid when the job fits his organization and plant because he knows just what the costs have been on similar work, and he may have just the plant needed. It is expensive to investigate prospective work, and this "over-head" is only paid for from the jobs that are obtained. Anything that will reduce the "over-head" benefits the industry.

Recently, an engineering paper carried two advertisements side by side for bidders on public work. One briefly gave the location, described the work, and the amount of each kind to be done; also it mentioned that the details could be obtained at the site (which was remote from the head office of the organization letting the work) as well as at two other locations convenient to bidders. The approximate bid price could easily be computed and the prospective bidder would know at once whether he should investigate. The other job was at least two days' journey from the office where the details could be obtained after depositing \$25; no plans were available at or near the site, and it is thought that most of the prospective bidders were remote from where the plans could be obtained. Whether the job would amount to \$100 000 or \$1 000 000, was left to the imagination. While the advertisement did give the date on which the bids would be received, it did not tell the place, whether at the site or at the distant main office.

After spending some time and money investigating a prospective contract, the contractor is apt to put in a bid, anyway, even although the job is larger than he can finance; therefore, the advertisement should indicate the probable contract price. The surety companies also would greatly appreciate this information because nearly every experienced contractor approaches his surety to ascertain whether a performance bond could be obtained, before putting in a bid on a large contract; and often the surety is asked to pass on the matter before the contractor is in a position to make his own approximate estimate.

The surety companies subscribe to engineering publications largely for the advance information to be found in the advertisements to bidders, and telegraphic submissions of bond cases often refer the surety to certain publications for details. Every time a surety authorizes a bond that should not have been authorized or fails to authorize one that should be written, the best interests of all concerned suffer.

The following form of advertisement is suggested:

.....(owner)..... will receive, publicly open and read, bids at its office at .....(address)..... at ....(hour)...., .....(date)....., for the construction of a ....., more fully described below.

(Here insert a paragraph giving location, accessibility (if desirable), and description in narrative or schedule form of the principal parts, items, or quantities. Include any pertinent facts regarding local conditions, the type of construction, the materials to be used, the size of buildings, etc., that will assist the contractor in determining whether his previous experience, plant, organization, and financial strength makes the work attractive to him.)

Approximate estimate of bid price between \$...... and \$......, certified check or bid bond of \$......, required, and performance bond will be \$...... (or ....% of contract price). After .....(date) ..... the plans, contract, and bidding forms can be obtained from above mentioned office, or from.....

(Dated)..... (Signed).....

The following principle holds:

- (21) It is to the owner's advantage to word the advertisement so the bidder can tell whether the proposed contract will fit his ability, experience, plant, organization, and financial strength.

C.—INFORMATION FOR BIDDERS, QUESTIONNAIRES

In the "Information for Bidders" is the place to state that the right is reserved to reject any or all bids and to tell the bidder where and how the bids will be received as well as what evidence, if any, he must present to qualify for the contract, should it be awarded to him. The contract later to be set up is supposed to be a fair "meeting of the minds"; hence, anything told the bidder in the "Information" that influences his conception of the proposed work, has much the same virtue as if included in the contract. It is believed the Courts have generally held this view.

Certain clauses in the general conditions of the contract, as on the bidding security, time allowed for signing the contract, etc., could with propriety be transferred to the "Information for Bidders", thus properly confining the contract proper to matter describing a method, detail, part, or condition of the consideration that one party gives the other. Hence:

- (22) Many contract forms would be improved if clauses on subjects which are active before the contract is signed were placed in the "Information for Bidders" instead of in the contract.

Every prospective bidder should have equal privileges in obtaining information about local conditions and whether or not alternate or informal bids will be entertained by the owner. It is decidedly unfair to let formal bidders expend their time and money preparing bids and then to award the contract to some informal bidder. If the owner is dissatisfied with the method he has specified and wishes to consider another one, the fair thing is to reject all bids or postpone the letting until all bidders can submit amended tenders for the work. That is:

- (23) Each prospective bidder should receive all the information given to any other bidder; and have the same opportunity to submit alternate or informal bids.

One of the best ways to minimize over-extension would be to give the prospective bidder a chance to limit the volume of new work he could receive at any letting, provided bids are taken on more than one job. The owner thus secures more competition per job and loses no economic advantage. The contractor is benefited because he has a better chance of getting a job when bidding on a large volume of work than on only the additional quantity that will fit his organization and ability to finance. Therefore:

- (24) Permit bidders to limit the amount of new work that may be awarded to them at any letting.

Most constructions supervised by architects are built amid urban surroundings where materials like sand and crushed stone are staple commodities with fixed prices. Many jobs supervised by engineers are at remote places where even the water supply may influence the cost. All specifications call for "clean and sharp" sand; but many localities cannot produce such a material although the local sand has been used satisfactorily. The engineer will secure much lower bids if all local sources of materials are investigated in advance. The writer recalls a case where it is thought an advance expenditure of \$500 by

the engineers would have saved a very large sum, possibly several hundred thousand dollars. Principle (3) is also pertinent to this subject. The best plan, then, is to:

- (25) Investigate local facilities and materials and furnish the information to all bidders.

Among contractors, engineers, and architects, there is a tacit understanding that the owner will proceed with the award within a reasonable time after receiving bids; but every now and then a contractor finds himself the low bidder with no definite idea of when, if ever, the contract will be signed. Such a delay is unfair as he hesitates to bid on other work; also his bidding security is still in the hands of the owner, and it may be difficult or impossible to obtain additional credit with which to bid on other contracts. As long as the bid is outstanding it is a potential contract and it affects his "responsibility" for other work. It is only fair, therefore, to:

- (26) Specify that within thirty days after receiving bids, the award will be made or all bids will be rejected.

In a few States the statutes require that the engineer's estimate of quantities and bid prices on highway work be made public in advance of the receipt of bids. This is against the best interests of the States, as it makes it too easy for inexperienced contractors to prepare bids. What may be a fair price for an experienced contractor with full equipment and a good organization may be wholly inadequate for a beginner. If the bidder is qualified to construct the work, he is qualified to prepare his own estimate. It is proper and desirable to tell the prospective bidder the approximate bid price within limits, but not to give him a detailed estimate or to ask him to bid on a percentage of the engineer's estimate as is often done. Therefore:

- (27) Do not give prospective bidders detailed estimates of proper bid prices on road or similar work.

For building work, where lump-sum bids are generally required, bidders must estimate the quantity of each item before they can fix the price. This is a laborious operation on a large building, and the cost is added to the bid price. Why should the owner pay the expense of ten, or more, quantity surveys on one job when he can provide one survey to serve all bidders, and at the same time bring all bidders into true competition on the basis of price only? In many localities groups of contractors find many advantages in having joint quantity surveys made. Any such plan requires distinct drawings and specifications, as uncertainties are bound to be uncovered by those preparing the quantity surveys. Furthermore, corrections made before the work is offered for bidding, lead to lower bids. As a general principle:

- (28) It is economic for owners to offer quantity surveys to bidders on building work.

Many advertisements for bidders are worded as if the owner were conferring a great favor on the contractor to permit him to bid—in fact, some owners charge the contractor a good fee for the plans. In reality, the favor is extended by the bidders because it costs more to prepare the bids than to

provide contract documents. After a bidder has qualified it is to the owner's advantage to loan him without charge all the contract documents he really needs in order to prepare an estimate carefully. Making it easy and inexpensive to bid is bound to be reflected favorably in the price and a \$100 expenditure by the owner for additional sets may return him thousands of dollars when the bids come in. Many parties as sub-contractors, material men, and sureties have a proper interest in reviewing the contract documents carefully before the bid is tendered.

Frequently, when deposits are taken, the time within which the plans must be returned is given as seven days after bids are received, and some advertisements state that all the documents must be returned with the bid. This is unfair, especially to parties who may have given sub-bids. In one metropolitan district sub-contractors on a certain class of work had so many disputes with contractors that they announced a decision to retain the drawings and specifications until such time as their bids had been definitely rejected. They had been asked too many times to perform at the old prices after changes had been made by the owners subsequent to the receipt of bids. Until all bids are rejected or some bid is accepted, the matter is open; therefore, the return of plans should be based on a period starting from the award of the contract or the rejection of all bids instead of from the date bids are received. A 14-day period is suggested as a fair condition. To sum up:

- (29) Be liberal rather than close as to the number of sets of the contract documents given to prospective bidders. Do not charge for these, nor ask for their return in less than fourteen days after the award or rejection of all bids.

Some contractors, apparently, get a great deal of satisfaction in bidding high without any desire to receive the award; others put in high bids merely because the engineer or architect asks them to estimate the jobs and they desire to remain in his good favor. Still others, having employed estimators, think they must keep them busy. A complimentary bid is disturbing and serves no real purpose. Often it causes difficulty for the low bidder to obtain a bond, or credit from his bank, because a few very high complimentary bids from contractors who are known to have a good knowledge of costs, make it appear as if the low bidder had greatly under-estimated the job and, therefore, will have a losing contract. Hence:

- (30) Engineers and architects should not encourage contractors to submit complimentary bids.

Available local facilities have a considerable influence on the prices which must be paid for certain constructions. Engineers have been known to increase the prices on their own contracts by letting so much work within a short time that there is no real competition as each contractor having the requisite plant is reasonably sure of obtaining all the work he desires. A certain owner always tried to spend the large sum available at a rate about 50% faster than the contractors could work, due to limited facilities for labor, materials, and transportation. As a result bid prices constantly rose although

the contractors failed to make profits on most of the work. A large number defaulted and others withdrew after suffering large losses. In other words:

- (31) To obtain economic bids, do not let more work than can be readily performed.

The allowance of the customary week or ten days after the award within which the contract must be signed and the bond given is often much too short and fourteen days should be allowed instead. The surety companies are hard pressed at times to underwrite bond cases, secure re-insurance from other companies, etc., within the short time available. With the extra days a case could be presented to the surety by mail with all the supporting documentary evidence, giving the underwriter a clear-cut picture, instead of rushing the case through by telegraphic presentation. It is on the side of conservative contract bond underwriting and does not really delay the actual beginning of the work because the contractor starts on his preliminary arrangements just as soon as he receives the award. Therefore:

- (32) Allow fourteen days after the award for signing the contract and giving bond.

A commendable practice is growing; the prospective bidder is required to fill in a questionnaire form demonstrating his responsibility before he receives the bidding forms or is awarded the contract. It is unfair to encourage him to bid and perhaps later deny him the award, if low; also it is thought that a contractor who has too much work on hand to warrant his being allowed to bid will make less disturbance if disqualified before bidding than after finding himself the low bidder. The forms are still quite new and undoubtedly changes will be introduced from time to time. Few of them direct an inquiry regarding outstanding bids or the amount and status of other contracts on hand, and this is a serious omission because the volume of work is an element which enters into any determination of responsibility.

One form asks the bidder to describe the methods or plant he will use if awarded the contract. This is an unfair question to ask of an experienced contractor. If the engineer wants a certain kind of plant used he can specify it, but if the contractor has to produce a specified volume and quality of construction work he should be allowed the greatest latitude in the selection of methods or plant. The construction industry owes much to the pioneers who have dared to use new processes and thus have found a cheaper and perhaps a better way of producing an old form of work. Why should the contractor disclose his methods before the contract has been awarded to him, especially as all bids may be thrown out and his competitors may consider the new method at the re-letting? In short:

- (33) Use questionnaire forms to qualify prospective bidders instead of to justify awards.

#### D.—BIDDING SECURITY

Bidding security is not generally required on private construction work; but on public work usually a deposit with the bid of either cash, Government bonds, a certified check or cashier's check, or a bid bond is required. At times, the bid must be accompanied by a letter or certificate issued by a

corporate surety company stating that it will write the contract bond for the bidder should he be awarded the contract. The bidding security is supposed to be a guarantee deposited with the owner binding the bidder to execute the contract and file the required contract bond should the contract be awarded to him.

References to the bidding security are generally included in the advertisement and "Information for Bidders". In many proposal forms the clause stating the conditions under which the bidding security is deposited as a guaranty fund for the owner's protection is decidedly unfair because it provides that, if the contractor fails to execute the contract and file the bond after an award, the fund is forfeited to the owner. The measure of damage to the owner is the difference between the bid that was not executed and that of the next, or some other bidder, who qualified. The owner after thinking so well of the contractor as to encourage him to prepare and tender a bid is treating him rather harshly to turn any possible misfortune to his own advantage.

The amount of the bidding security is generally about 10 or 15% of the contract price. It is desirable that the owner state a definite amount rather than a certain percentage of the bid price, because the bidder may not know what he will bid until just before the bid is tendered. The practice of some public work bodies seems to encourage the financially weak contractor to bid on work beyond his capacity as they graduate the size of the security required up to a maximum of, say \$25 000, which sum would apply to any contract of more than a certain amount. In one case the maximum security of \$15 000 was supposed to give the owner protection on a contract of nearly \$500 000. A \$50 000 bidding security would have been much more appropriate. It is best, therefore, to:

- (34) Designate a lump sum for the bidding security in an amount from 10 to 15% of the probable contract price, and condition its receipt so that the measure of damage to the owner, if the bidder fails to execute the contract and file a bond, is the difference between the amount bid and the amount for which the owner may be able to award the contract within a reasonable time.

Many engineers, contractors, and surety companies believe it is desirable to abolish the use of bid bonds and hold strictly to the use of cash, Government bonds, or certified checks. The requirement that checks shall be filed is increasing and bid bonds may soon be a thing of the past. Almost all bidding checks are borrowed from a bank because they may be on deposit for some time after the bids are opened, and contractors seldom have enough surplus cash to permit a considerable sum to be taken from the business. This borrowing is really desirable as it brings them together at a time when the banker may give the contractor some good advice against taking on more work than can be easily financed. Many contractors after such talks have wisely decided not to bid. In all cases, then:

- (35) Do not permit bid bonds as bidding security.

The letter issued by a surety company stating that it will write the contract bond if the bidder is awarded the contract is called a "bid letter" by

the surety, and is handled by it just the same as a bid bond. All the reasons that make bid bonds objectionable apply equally to bid letters. The owner fixes the amount of the certified check and should make it large enough to supply the protection desired without trying to bring in a surety company to bear part of the load. It is in line with conservative underwriting if the surety gives no letter or certificate to the owner when bids are received, because seldom has the surety had time to give the case the full investigation needed. Therefore:

(36) Do not ask for bid letters.

#### E.—AWARDING THE CONTRACT

Often bids have been prepared at considerable expense, and it is not treating the bidders fairly unless they are accorded the privilege of being present when the bids are publicly opened and read, as this is the only guaranty that there is real competition. Otherwise, the bidder is apt to suspect that the job is "set" for some favored contractor. Public opening is almost universal when public money is to be expended, but on private work there is still a considerable proportion of secret openings. It is claimed that often after a secret opening the better class of contractors are asked to cut their bids to meet the figures of irresponsible contractors who have nothing to lose and who therefore bid much lower than good construction work can be produced, and who may have been asked to bid for this reason. So flagrant has this practice become in certain localities that the reputable contractors have found it to their advantage to file duplicate bids, one with the owner and the other with some designated person who later gives each bidder a tabulation of the bids. Naturally, the owner does not get very far in "peddling bids" when the best contractors know all the details. So it is good policy that:

(37) Bids on public or private work should be publicly opened and read.

Scarcely any reputable contractors are averse to bidding on important contracts located in other places. It is generally considered strictly proper for contractors to bid on distant work and for owners to invite such bids. Frequently, however, an out-of-town bidder is low and a local contractor is next; then the greatest pressure is brought to bear on the owner to let the work to the local bidder under the plea that "all the money should be kept at home". Such an award would be unfair to the outside bidder who was encouraged to bid and who believed, tacitly perhaps, that if he was low, he would receive the award. If only local bidders are desired, the advertisement should state this condition. Even should the out-of-town contractor do the work, most of the money will stay at home because it is largely the local materials that will be used, also local labor; and the contractor only takes away with him the profit, if any, at completion. If he loses because he bid under the local bidder, the out-of-town contractor might, in fact, make a substantial contribution to the community. The rule should be:

(38) Award the contract to the lowest bidder if he is qualified, irrespective of what a local bidder has bid.

No owner wants his work performed by an irresponsible contractor, nor do engineers desire him to undertake contracts supervised by them. It is supposed to be the professional duty of an engineer to advise the owner regarding the low bidder and to urge the award to a responsible contractor.

Any contractor who is dishonest, tricky, and bears a bad reputation with those for whom he has done work is, of course, irresponsible no matter how many ill-gotten gains he possesses. Fortunately, there are not many such in the construction industry, and the contractors who are doing the greater part of the large yearly construction programs are men with just as high ideals and character as will be found in any other large industry.

However, merely being honest does not make a contractor "responsible" to undertake a large contract. In addition he should have ability as evidenced by his past experience and record; an organization suitable for the proposed work; and sufficient working capital or net quick assets to finance the operations and reasonable additional costs. These qualifications should give a fair assurance to the owner (or a surety company) that the contractor is well able to complete satisfactorily (a) all the unfinished contracts on hand; (b) the new contract in question; and (c) all the contracts subsequently taken until the new contract has been completed and all bids have been paid. When a contractor gets into trouble on one job it soon spreads to all his contracts; therefore, the entire volume of work he is obligated to perform is a very important element in determining his responsibility, although many do not give this element due weight. Assuming the contractor is otherwise qualified, his responsibility is determined by the ratio his financial strength bears to the total volume of work he must perform.

When the contractor is working well within the proper ratio, he should be a good risk for himself, as he will probably have sufficient assets to meet an ordinary financial strain if necessary, and so will continue in business. When he is over-extended or suffers bad luck, he may be forced into bankruptcy because credit quickly becomes afraid and runs away in the face of trouble—that is, all credit except the bonding credit which has to stay because a contract bond is a non-cancellable obligation. While the ratio of the financial worth to the total work should always be determined, so that it can be duly considered when judging the responsibility of a contractor, it is doubtful if any fixed ratio rule could be applied generally, because contractors vary in their ability to overcome difficulties and because many kinds of work are inherently much more hazardous than others. Probably no two persons will reach the same conclusion on responsibility, although experienced surety company underwriters will frequently agree on how much work of a certain class a contractor should undertake at any one time.

Many surety companies have a basic ratio rule about as follows: Assuming the contractor is capable, experienced, and has all the plant and organization needed, he should have unquestioned net quick assets of not less than 10% and other assets of an additional 10% of the total volume of work to be performed. Unusual ability and a kind of work that is not hazardous might lead the surety to reduce this ratio, while work of a hazardous kind,

or under unfavorable local conditions, would lead the surety to desire more working capital in proportion to the volume of work.

Many engineers, architects, and contractors do not recognize any ratio rule in determining responsibility, but classify a contractor according to the size of the contracts previously performed by him without any consideration of the number he is qualified to handle and finance at any one time. A contractor who has a large plant and little working capital is a poor risk, even on a contract that is well inside the ratio, and is taken when he has no other work on hand, because, in all probability, he will soon take on other contracts in order to keep all his plant at work and then will have too much under way at one time. Too much plant without corresponding net quick assets has wrecked many contractors, especially in the road-building business. A contractor can often make more money closely supervising one contract than in trying to handle several, some perhaps at a distance, and this has been proved over and over again in the financial statements filed with surety companies.

While it is comparatively easy for an engineer to follow the progress being made on a contractor's work on hand, it is not so easy to analyze his financial statement and determine what allowances should be considered in arriving at the net quick assets and net worth. All parties habitually dealing with credits will disallow or greatly scale down all obscure items; contractors, unfortunately, have no standard method of keeping their accounts or preparing financial statements, so that many asset items cannot be evaluated without the supporting information.

Anticipated profits are frequently included, and many contractors think every dollar expended on a contract is bound to come back accompanied by the estimated profit. Notes receivable may have been given in payment for a junior interest in the co-partnership or corporation which conducts the business, and these really add nothing that has a quick sale value. Stocks and bonds may appear at inflated values. The contractor or a certified public accountant can say under oath that the statement shows the true condition of the books, but such an oath does not necessarily determine what net quick assets or net worth should be allowed. All these considerations lead to the principle:

- (39) Ascertain the ratio between the contractor's financial strength and the volume of work he is obligated to perform. Use this as an aid in determining his responsibility before awarding the contract.

## DISCUSSION

L. C. WASON,\* M. Am. Soc. C. E. (by letter).—This paper is eminently fair, comprehensive, and complete, and the writer endorses each of the thirty-nine recommendations, except in a few cases, as follows.

The author calls for small-scale drawings, Principle (11), but the writer thinks that these would be expensive and unsatisfactory, while a photostatic reproduction of the contract plans would be simple and inexpensive.

The Aberthaw Company has sometimes followed the method suggested in Principle (12), but has found it somewhat unsatisfactory because the engineer or architect has used these items for purposes of adjusting or computing extras when they were not compiled for such a purpose. When compiled for payment purposes only, they are sometimes unbalanced for one reason or another, and, therefore, if used for another purpose, such as computing extras, they may do a rank injustice.

To overcome this objection the Company has followed the practice of making payments at a certain point of progress which could be easily determined as, for instance, on a building: Completion of foundation, the completion of first floor, second floor, etc., the roof, and other progress points in regard to interior finish and completion. This method has been satisfactory to both the engineer and the contractor.

The writer agrees with the principle stated in Principle (13), but past practice has permitted the owner to withhold very large reserves, much more than are needed to protect him, and has tied up a great deal of the contractor's capital, whereas if the owner had retained only enough to protect himself and had paid the contractor the remainder it would have enabled him in many cases to complete his contract without a default, because he would then have enough cash with which to carry on his work and to pay outstanding bills. A clause should be added to the effect that only enough reserve be retained by the owner for self-protection and all the surplus be turned over to the contractor.

The writer agrees with the principle stated in Principle (26), but would cut the time to ten days. The owner knows the maximum amount he is willing to put into the undertaking, and ten days is ample time to discuss and digest the bids received and to determine whether he wants to go ahead.

As for the principle stated in Principle (27), the writer suggests that the method for the engineer to follow is to read his own estimate into the record of the bids when opened. This is being suggested as a method for the Federal engineers when they receive bids and plan on doing the work by the day as they have on a number of occasions. Then, of course, a direct comparison is available between the engineer's estimate and contractors' bids, and by this method is not incurred the objection which Mr. Bush suggests, with which the writer agrees.

As a whole, Mr. Bush has made a very comprehensive and important contribution to the relationship of engineers and architects with contractors, which should have wide circulation and careful reading.

---

\* Pres. and Treas., Aberthaw Co., Boston, Mass.

CHARLES J. BENNETT,\* M. AM. SOC. C. E. (by letter).—The author apparently is familiar with the letting of contracts. He approaches the subject from the standpoint of an engineer's interest in securing satisfactory contracts and resultant excellence in work. His viewpoint is that of the surety company. Nevertheless, the paper presents a broad discussion on the subject of contracts and specifications and is worthy of careful perusal by engineers. Attention is called to the necessity for clearness and continuity in writing specifications and including in the contract form carefully written clauses covering the character of the work to be done and the conditions specified. Experience in letting a large number of contracts convinces the writer that much work is necessary before engineers and architects come to the point where the contract and specifications will be sufficiently clear to advise the prospective bidder just what he has to do. The paper gives much information which will aid in securing this desirable result.

The writer is convinced that the average specifications and contract fall far short of achieving the ideal. Particular attention is called to the fact that ambiguous clauses may be interpreted by the engineer to the disadvantage of the contractor and in some cases at the expense of the owner. Emphasis must be laid on the necessity for drawing each contract and specification carefully to cover the particular work in hand. In other words, no attempt to apply a standard specification to a particular job will be successful. It seems trite to state, but it is nevertheless true, that the greater the care in preparing these documents the better the results in securing a reasonable cost and excellent work. The author discusses thirty-nine topics all of which are valuable in studying the question of contracts and specifications. Difference of opinion may arise on some of these principles, but, in general, the paper is sound and reasonable and merits careful reading by engineers.

The writer does not entirely agree with the author regarding the removal of the surety's liability (Principle (7)). His experience has been that often labor is not paid regularly and that protection to this particular item in the cost of construction should be included in the liability bond. The writer is willing to question also the statement that protection to sellers of equipment (Principle (8)) should be removed and would qualify it by saying that that portion of equipment bills which is properly chargeable to the work in hand should be protected by the surety. He is quite in accord with the author, in the elimination of guaranties for maintenance.

CHARLES F. CHASE,† M. AM. SOC. C. E. (by letter).—The first part of this paper interests the writer particularly because it emphasizes some matters on which the American Institute of Steel Construction as well as the Structural Steel Board of Trade of New England and other organizations have been working. The point is that so many architects and even engineers leave it to a contractor or bidder to guess what may be required when the specifications contain such clauses as:

"Furnish all steel, or other materials, whether indicated by the drawings or specifications or clearly required to carry out the intent of the design."

\* Cons. Engr., Hartford, Conn.

† Pres., The Berlin Constr. Co., Inc., Berlin, Conn.

The architect or engineer is supposed to be paid by the owner to make plans and specifications that will give the owner what he wants and to give a contractor complete information as to the requirements. If such plans and specifications are not complete and definite there are as many guessers as there are bidders and, in many cases, the lowest bidder or guesser, if he secures the contract, has undertaken something which will make trouble for him from the start. If all uncertainties are removed the owner will be benefited, for he will pay no more (probably less in the end) and will get what he wants.

The writer cannot understand why so much is left to the imagination of a steel fabricator. The same thing applies to all construction and from personal experience, the writer knows that many contractors base their bids on what they know of the architect or engineer as well as on the plans he prepares.

The matter of contractors' bonds is also a very vital one, and all sub-contractors are interested in what protection they get if the general contractor defaults. Many general contractors assume obligations which they are unable to finance. The result is that sub-contractors have to help carry the work and this can be done only at increased cost to themselves, or, in case of a default, they are the greatest proportional losers, unless the surety company is bound to pay them in full. Of course, if the surety company assumes this obligation, the premium has to be made commensurate with the risk and the public, in the end, pays the bill.

WILLIAM E. RUDOLPH,\* M. A. M. Soc. C. E. (by letter).—The author mentions the unfair "peddling" of bids. This practice does not appear to be confined to instances where bids are opened behind closed doors. It is now quite common, after a public opening, to have estimates re-compiled by three or more of the low bidders under the pretense of revision in plans and specifications, although the changes may be of distinctly minor importance. Naturally, each of the "favored" contractors knows what his competitors have bid and what figure he must submit if he wishes to get the work. The result too often entails loss for all parties concerned. When minor changes in plans or specifications are to be made, such as to bring the cost of a job within an appropriation, it would appear a fair rule to do business only with the lowest qualified bidder.

With reference to the economy of furnishing quantity estimates to bidders, contractors are being circularized by estimating agencies which offer to sell such estimates on any particular job. How reliable many of these estimates may be, is an open question. Their sponsors must be receiving some return for their efforts or the practice would not continue. Certainly the engineer or architect who prepared the plans is better qualified to furnish such quantities than unknown outsiders.

In support of Mr. Bush's Principle (29), there appears to be no justification for requiring a contractor to return his set of plans and specifications with his bid. What other proof has he of the amount of work which he has bound himself to perform?

\* Chf. Engr., Green-Muth Bldg. Corp., Rockville Center, N. Y.

LAZARUS WHITE,\* M. A. M. Soc. C. E.—This is a very valuable paper, because the contract under which one works, either as engineer or contractor, is perhaps the principal instrument in the accomplishment of that work. The relation of the engineer to the contractor itself contains the human element, and as no contract ever automatically executes itself without the aid of human beings, one should consider the contractor, in this relation, as a human being entitled to justice. He takes all the responsibility and risks his capital and reputation on the successful performance of the work, and in that he is perhaps aided by the surety company.

The most ancient definition of a contract is the clearest—a contract is “a meeting of the minds”. One party wants something done, and he asks the other party, “How much will you do it for? Here are the conditions”. What does that imply? Does it imply that the first party has the option of saying “even if the conditions vary—no matter how much from the conditions described—the price still holds”? That is practically what all contracts endeavor to do. Instead, the contract should state:

“These are the conditions, and if done under these conditions this price will hold; if the conditions are found to be different, then we will make necessary modifications and adjust the price.”

The speaker happens to know of cases where that has been done, and the result was remarkably cheap work. The contractors assumed that the conditions described would be met, and they knew that the engineer with a strong sense of justice, would modify the prices if conditions were found to be different. If a contract is based on certain stated conditions, and those conditions are found to be different, the price is modified so that the contractor “comes out whole”.

In city contracts elaborate borings are sometimes made; but despite that all the information is covered with waivers, practically admitting inaccuracies; and an attempt is made to deprive the contractor of redress in case the conditions are found to be different.

Another condition that has crept into contracts is that the engineer is supposed to act in a judicial capacity, and rightfully so. Nevertheless, he attempts very often—perhaps the lawyers insist that he do so—to give himself arbitrary and dictatorial powers. The contractor must accept his decision and, by the wording of the contract, has no appeal. The engineer at best is paid by the other side; he owes his position to that side. Never in the history of the world have men been of high enough caliber not to be influenced by such a situation; and yet an attempt is made to deprive the contractor of the right of appeal. Of course, that has been upset by the Courts. No engineer or lawyer can deprive a man of the right to go to Court and ask for relief for any injury from which he even thinks he suffers.

Various technicalities, however, are put in the contract, to the effect that claims must be made within ten or fifteen days after a loss is incurred, and in case the contractor does not do it within the time stated, it is supposed to act as a waiver and he is deprived of the right to go to Court. That has usually been upset by the Court, but there is danger in it. It is often impossible for

\* Pres., Spencer, White & Prentiss, Inc., New York, N. Y.

the contractor to make his claim within the time set. His loss frequently cannot be computed until the end of the contract, and he should be allowed to file claims at any time until the work is completed.

The speaker cannot see the logic of Principle (13). The owner is to retain a greater and greater sum of money as the contract approaches completion, on the theory that the contractor is more likely to fail at that period. At the same time the paper contains an argument on the value of sureties and that seems inconsistent. The surety is largely expected to ensure that the job shall be completed, and yet it advocates the retention of a large part of the money for work actually done. A man should be paid for what he does, and no large amounts should be retained. He risks his capital and his reputation; he puts up a bond. Why should he not be paid for work actually performed?

A bank is apt to press a contractor at the end of the work for the payment of money loaned him. That, no doubt, is quite proper; but, at the same time, if the money he has earned is not paid him, how can he pay the bank?

The author discusses bid bonds (Principle (35)). To require a bid bond is in a way asking the surety company to do something with which it is not familiar. The surety company is required to guarantee a contract of which the price has not yet been made. The bid price, for instance, might be for \$5 000 000 on a \$15 000 000 contract, and yet the bond holds. That is really an injustice.

The number of contracts let is constantly increasing, and work is continuing in larger measure to be let by contract. Now, the reason it is not done directly is that it cannot be done so well, nor so economically as by contract. The engineer, whether he represents a community or a company, does not have the same freedom that a contractor has in selecting his men. He is hampered by various limitations and by the politics of his own community or the politics of the company he is with; whereas if a contractor operates on any such principle he is quickly eliminated by his financial losses.

The author describes an ideal contract. Those who examine the contracts recently let by the Board of Water Supply of New York City will find a fairly close approximation to the conditions given in this paper. No matter how perfectly a contract may be drawn and its conditions described there remains a very strong economic factor for the contractor to evaluate and that is the efficiency of his own force. What is the scale of wages going to be for the next few years? What will be the price of materials? These risks he is willing to take; that is his business.

A. E. WALDRON,\* M. AM. SOC. C. E.—This paper is very interesting, but the speaker fears that, if it is accepted, it will lead the engineer into a pitfall. It raises the question of the relation between the bonding company and the engineer. It sets forth many points to be covered by information to bidders, the specifications, or the contract. All these factors, no matter how desirable they may be, are those which the bonding company would like to have the contractor know. However, each item of information the engineer gives increases his responsibility to some extent. The speaker doubts that much information tends to reduce prices. When the contractor knows all

\* Col., Corps of Engrs., U. S. A.; with N. Y. C. R. R., New York, N. Y.

hazards to be encountered, he is apt to bid higher than if he has to take a chance here and there. When chances are to be taken there is always a shaving of prices in order to "beat the other fellow". Moreover, when the engineer gives a great mass of information, much of it is likely to be speculative and may eventually prove to be incorrect. Then, if the contractor fails, the bonding company has good grounds to plead lack of responsibility because the information given was erroneous and the contractor did not find conditions as specified. The safe course is to give only such information as is absolute fact and is certain to reduce bid prices and not that which the bidders can ascertain for themselves through reasonable deduction.

With all the information given, as recommended by the author, the bonding company has nothing to do but to collect its fee and rest content. If the contractor goes wrong, then, the engineer is sure to have blundered in some of his information and the bonding company's responsibility is nil. It is not bonding the engineer.

A legal contract is defined as a meeting of minds. After such meeting of minds—that is, after a contract has been let—what is the usual procedure? The engineer tries to get as much as he can for his employer; the contractor tries to do as little as possible in order to increase his earnings. With all conceivable information given, thereby removing all deductions, the contractor becomes nothing more than a labor and construction boss. For satisfactory work under contract, the successful bidder should be more than this; he should bring some engineering ability to the job. If not, there are no good reasons why the engineer, knowing all conceivable conditions, should not do the work under his own direction or by hired labor, etc. All the things a contractor knows in reference to his job, the engineer should know to be able to decide whether or not bids are reasonable. Therefore, why should he not do the work himself?

In the case of public work there are conditions that make a contract desirable, but similar conditions make it, also, desirable from the bonding company's point of view, for the engineer to specify everything. On private work, however, the contractor's profit, the bonding company's profit, and the various contentions that arise, are all inducements for the owner to do the work himself.

It is stated that the engineer should keep the bonding company informed of various things and facts. The speaker cannot see the wisdom or profit in such procedure. What responsibility does the engineer have to the bonding company? It is only when the contract is annulled that the engineer should begin to deal with the company. To do otherwise, especially on public work in which money that is disbursed is passed upon by comptrollers, is "a step in the wrong direction".

At times, it seems as if lawyers have made engineers afraid to back up their work. However, the real situation is that engineers have learned that it is useless to buck the procedure that causes changes in the phraseology of specifications. The lawyer's word or advice is accepted and a superior officer gives orders that such and such be incorporated in the specifications, because some judge or jury decided a particular and restricted case in a certain way,

and thus specifications include peculiar provisions. There are errors in law as well as in other professions. It is not the facts that lead engineers astray, but the deductions made from facts.

A. JORDAN BERNSTEIN,\* M. Am. Soc. C. E.—The speaker considers this paper to be most excellent and one of the most interesting that he has ever read. He wishes to discuss it only as it applies to building construction in which the owners are individuals or corporations and not governmental agencies.

With reference to the method of determining the proper monthly payments to be made to a contractor the author states in Principle (12):

"A much better practice is to have the contractor, as soon as the contract is signed, submit a schedule of all the component parts of the work with prices attached, the total of which will equal the lump-sum contract price."

The speaker approves of this method, but he would caution the engineer against a practice on the part of some contractors who arbitrarily declare high prices for items that are done near the beginning of the job and low ones for those that occur near the end, for obvious reasons.

In Principle (13) the author makes the point that the owner needs to retain a greater reserve near the end than near the beginning of the work on account of the greater likelihood of a default at that stage. There is one condition near the very end of the job under which the suggested retention of a greater reserve works an unjustifiable hardship on the contractor. The work of putting the finishing touches to a building sometimes stretches over a considerable length of time. This may be due to a lack of energy on the part of the general contractor; but more often it is caused by the delay on the part of a contractor who is employed by the owner directly and over whom the general contractor has no control. At other times, it may be due to prospective tenants whose decisions with regard to partitions, store fronts, etc., must be taken into account. Whatever the cause, the general contractor is faced with the unpleasant fact that, although the items that still remain to be done may represent only a few thousand dollars, he may have a huge sum tied up in the 10% or 15% reserve, on the technical ground that he has not finished 100% of the work.

This safeguard of retaining a reserve, as well as most of the safeguards to be found in the average contract form, is in favor of the owner as against the contractor. Apparently, little thought has been given to protecting the contractor against an owner who has over-extended himself financially and who compels the contractor to accept paper as payment after "stringing him along" for a considerable time subsequent to the completion of the job.

In Principles (17) and (25), the author urges the engineer to furnish drawings and specifications that are more detailed and complete than is often the practice, and to furnish more information regarding local conditions. While the speaker agrees with this recommendation, he is of the opinion that there is little cause for complaint on this score when the engineer is allowed enough time for the preparation of his drawings and specifications, and more

\* Cons. Engr., New York, N. Y.

especially when he is paid adequately for his services. Unfortunately, the engineer often accepts work at too low a price and frequently agrees to complete his work in a very short time. Under those conditions the plans cannot be entirely complete and the engineer is generally compelled to copy the specifications of a previous job, making only such modifications as suggest themselves in the hurry of getting the drawings and papers ready for bids. Discrepancies between plans and specifications are the result.

The author makes an excellent point when he advises the exclusion from contract forms of clauses which properly belong under "Information for Bidders" (Principle (22)). It is surprising how persistently contract forms which are replete with irrelevant matter and so poorly worded that they cause inconvenience to all parties, continue in general use.

In Principle (37) the author urges the public opening of bids even on private work. The speaker approves of this method, provided only that it is recognized by all parties that there may be a great difference in the capacity, the willingness to co-operate, the sense of fairness, and the character of the several bidders (all of whom may be entirely responsible), and that it is proper, therefore, to pay to one contractor somewhat more for a particular job than to another.

The author recommends that the contract be awarded to the lowest bidder if he is qualified, irrespective of what a local contractor has bid (Principle (38)). The speaker would point out that the amount of a bid is not the only factor that determines the final cost of a building. An out-of-town contractor is more likely to get into difficulties with the local labor unions or with the municipal bureaus than a local man, thus possibly delaying the completion of the building and, therefore, increasing the owner's carrying charges. Furthermore, a local contractor can generally secure the best local mechanics. The out-of-town contractor, therefore, should expect to lose the contract unless his bid is considerably less than the local bid.

After erecting about sixty buildings in a dozen cities the speaker has come to the conclusion that the best written contract affords but little protection against a contractor who is incompetent or who is too preoccupied with other work to live up to a specified schedule. Therefore, he would recommend that the engineer draw the contract with the greatest care and provide every possible safeguard; but, above all, that he award a contract only to bidders who have earned a reputation for ability and for sterling character.

ERNEST NICHOLSON,\* Assoc. M. Am. Soc. C. E.—In reference to Principle (3), the speaker knows of several instances in which details were omitted from the plans so that they were incomplete when the bids were taken and the contracts signed; when finally completed by the architect they had been so elaborated that Court action was necessary to straighten out matters. Frequently, only simple details are required, but if these are lacking, it becomes necessary to bid high for protection to the contractor or sub-contractor.

In New York and Pennsylvania the charges for bond premiums vary as mentioned under Principle (7), in connection with public work, such as public

\* Field Engr., Aetna Casualty & Surety Co., Hartford, Conn.

buildings. The premium in New York is two-thirds that in Pennsylvania, the difference being due to labor and material liability under the bond in the two States.

In reference to Principle (24), one State in New England will not allow a contractor to bid on several road jobs at the same bid opening with the option of withdrawing from some of them. In New York State bidders are allowed to withdraw other tenders if they are low on one or more—the withdrawing being necessary as soon as the bids on the previous job are read. In Pennsylvania, the extensions and additions are checked by the State engineers before the following job is read, and the contractor is then sure of his arithmetical work before being called on to decide if he wants his other bids to be considered. It is obvious that in New York and Pennsylvania a small operator has a better chance of securing a job and the States, in turn, have the advantage of securing lower bids at times,

An example might be quoted in support of Principle (26). In connection with a certain State road contract, the job was held up by an injunction just after the contract was signed and the bond delivered. After considerable delay, and when it was thought the work would never be built, the contractor took on another contract in an adjoining State. Later, the objection to the first contract was removed and the contractor tried to run both jobs, but this volume of work was too much for him and he defaulted.

Regarding Principle (27), it is known that when estimates are given out prior to the bid opening, some contractors of doubtful experience, ability, and resources put in bids on the basis of a certain percentage of the engineer's estimate.

In reference to the furnishing of quantity surveys, as mentioned in Principle (28), the speaker knows of one city where the contractors bidding on a job divide the cost of having a survey of quantities made for the use of all, in order that such cost would not be levied on each. Many small contractors compute two and three jobs per week, the cost of which must finally come out of a future job. In some places the contractors sign an agreement to add a fixed sum to their bid and then the low bidder shares this amount with the unsuccessful ones. The speaker understands that in England it is becoming the general practice among architects to furnish bidders with a detailed quantity survey.

ARTHUR W. CONSOER,\* M. Am. Soc. C. E. (by letter).—The author presents an argument in favor of simplifying and rationalizing the letting of contracts by competitive bidding by improving the quality and completeness of the plans and specifications and contract forms prepared by the engineer. This is intimately connected with the problem of adequate engineering fees for practicing and consulting engineers and adequate appropriations for the work of public or corporation offices engaged in engineering work. Improvement in the scale of compensation paid to practicing and consulting engineers and to engineering staffs will automatically result in marked improvement in

\* Vice-Pres., and Gen. Mgr., Consoer, Older & Quinlan, Inc., Chicago, Ill.

the preparation of plans and specifications and contract forms. Such improvement, in turn, will result in savings in construction costs and reduction of litigation with surety companies and other parties.

Rigid inspection and able engineering supervision are costly. An engineer who is operating on a low fee basis in a highly competitive field is very apt to specify results which the contractor must produce and to demand unreasonable maintenance guaranties instead of merely specifying workmanship and materials and relying on his own rigid inspection and supervision for satisfactory results. Inexperienced engineers, likewise, hesitate to assume responsibilities for their own designs and lean on the contractor by requiring him to be responsible for the final results. When unsatisfactory results on construction work are due to poor engineering design, the contractor should not be held liable under the contract.

Frequently engineers do not have sufficient control over the inspection staff. On public work, particularly, the appointment of political favorites as inspectors is regrettably common. Under such conditions engineers sometimes hesitate to assume full responsibility for the sufficiency of the plans and specifications, and attempt to solve the difficulty by exacting maintenance guaranties from the contractor and his surety. The practice of strengthening the position of the engineers in charge of public works by giving them closer control of the inspection staffs will facilitate desirable changes in contract forms in public work.

The cost to contractors of preparing proposals for competitive bidding can be reduced by improving the diction and "make-up" of advertisements for bidders. The author's suggested form of advertisement is clear and concise. However, the writer would suggest further that it should include a statement as to length of time that will be allowed for the construction period and that the manner of payment, whether in cash or bonds, should also be stated. On large projects it is helpful to the bidders if, with the plans, specifications, and proposal forms, there are included some airplane photographs and other views of the site of the work. There should also be a detailed sketch showing available railroad sidings for unloading materials, with information regarding rental charges for such facilities, and locations of approved available supplies of sand, gravel, or other materials, as well as a detailed list of approved material sources within convenient freight haul of the site of the proposed work. When underground or foundation work is involved, information should be supplied by the engineer in the form of descriptions of test pits or soil borings. If quantities given in a proposal form are known by the engineer to be in excess of the amount that will go into the work, prospective bidders should be apprised of that fact. Competition will be increased and prices lowered if the engineer will eliminate all lump-sum proposals and take bids only on the basis of detailed, accurate, quantity surveys. Such detailed lists of quantities are not only helpful in reducing the contractors' cost in preparing proposals, but also to the engineer in his preparation of estimates for payment to the contractors during the construction period, and in checking the accuracy of final estimates for payment based on actual measurements in the field.

A large source of expense to many contractors is the tendency of many engineers to inspect materials of construction on the site of the work only and to forego plant inspection. If specifications were written to provide for plant inspection the contractors on many projects would be able to reduce their estimated costs. The practice of culling paving brick and sewer pipe on the street has made many a contractor insolvent. Specifications for the qualifications of inspectors and field engineers might also be included with advantage. If a contractor bidding on a project knew that no one would be employed to inspect his work without having had at least five years' experience on construction work of a similar nature, he might be able further to reduce his estimated costs.

Whenever a new contractor bids on the writer's work, he is supplied with a copy of the "Standard Instructions to Inspectors" used in the writer's practice, so that such a contractor may gain some idea of just what type of inspection he may expect to encounter on the work. Many a foreign contractor is kept off a large project because of his lack of knowledge of the methods to be used by, and the characteristic attitude of, the engineer in charge. Anything that can be done by an engineer to remove all uncertainties regarding himself and his subordinates will increase competition and reduce construction costs.

Engineers, contractors, and surety companies are all interested in reducing waste in the construction industry. If the engineer can effect savings for a number of contractors by supplying certain information, rather than by forcing all bidders to procure such data individually, he should do so. Likewise, many of the reforms in administration of contract work let by competitive bidding, which are proposed by the author, will eliminate waste and reduce construction costs.

Most of such improved practice in letting work by competitive bidding will reduce construction costs and at the same time will increase engineering costs. The aim should be to strike an economical balance between the two factors. In many cases it will be found possible and economical to double the amount spent for engineering work without increasing the total cost of the project, inasmuch as engineering costs are a small fraction of the total.

F. H. STEPHENSON,\* M. A. Soc. C. E. (by letter).—The author has presented some very pertinent recommendations regarding a subject of major importance in engineering practice. Complete discussion of this paper will probably reflect the viewpoints of the engineers of the bonding companies, the contractors, and the owners. As an employee of a municipal corporation, the writer has the following comments to offer.

The author recommends that in the "Advertisement for Bidders" an approximate estimate of the cost of the work be published, giving an upper and a lower limit. The writer fully believes that, by reading the advertisement, the prospective bidder should be able to decide whether the work on which bids are requested is of the kind in which he is skilled and experienced and of a size to correspond with his financial status.

---

\* Engr., Water System, Dept. of Water Supply, Detroit, Mich.

On the other hand when State or municipal work is involved contractors cannot be refused plans and specifications. Very often these inexperienced people are anxious to get the engineer's estimate as a check on their own calculations, which may sometimes be wild guesses rather than figures backed by experience and former cost records.

With all things considered, the writer believes that a rather wide variation between the published price limits would often be a help and, at other times, a hindrance. In view of the wide divergence of bids made by contractors of apparently equal experience and financial standing, the upper price might well be 50% greater than the lower price.

The writer agrees with the author in Principle (34) that a designated lump sum as bidding security is preferable to a fixed percentage of the bidder's proposal to do the work. He believes, however, that the relation of bidding security to total cost should be a variable amount, depending on the size of the job. The sum of 10% on a \$1 000 000 job is considerable to hold as a certified check for two weeks or more while perhaps the responsibility and ability of bidders are being investigated. It seems reasonable and fair to stipulate that if the bidder fails to execute after being awarded the contract, he should be penalized only the actual loss to the owner by accepting the next highest bid.

The writer's experience does not accord with the author's statement that "labor really does not need protection because it will not work unless pay-rolls are promptly met, \* \* \*." Labor really needs even more protection than it is given at present. Material men also need protection, and the writer's experience has led him to conclude that even a bond does not furnish all the protection it should. The owner—whether it be an individual, corporation, utility, or unit of government—is primarily interested in getting certain work done at a fair price, and he desires to assist the contractor by helping to secure labor and material and at the same time to protect that labor and material from loss through no fault of either party.

JOHN C. WAIT,\* M. AM. Soc. C. E.—The author presents two conditions for the successful completion of contract work: (1) The choice of a capable and experienced contractor who is thoroughly reliable, financially and otherwise; and (2) the choice of a good surety company that is thoroughly able and willing to back him. Every one will agree that this would be an ideal condition for the owners, municipalities, States, and the contractors, but, practically, it does not exist.

Especially, in the City of New York, some of the greatest projects and the biggest contracts have been undertaken by unknown contractors without personal finances. Some contractors have done New York's greatest work and have gone, penniless, to the grave. Some of the greatest buildings, bridges, tunnels, and subways, have been successfully built by men who could scarcely be expected to undertake great work.

The policy that is recommended in this paper (see Principle (39)) is now developing in the municipalities and in the States; that is, the policy of investigating the financial strength and the experience of contractors.

---

\* Counsellor at Law (Wait, Wilson & Newton), New York, N. Y.

Public officials are being authorized by law to determine the reliability, responsibility, and capability of contractors, and they are doing so to the fullest extent. The great Manhattan Bridge was built by a contractor who owed his bank thousands of dollars; who did not even have funds with which to begin the work; who was opposed by all the steel companies in North America; and yet who built the bridge in the shortest time in which any suspension bridge had ever been built, and there was not one single complaint or lawsuit that followed its completion.

Now, why select contractors who are successful, who have great financial and political backing, and who have great experience, when there are others who are not so fortunate nor so successful, but who can carry out the contract. Some of the biggest public works being built to-day are by contractors who were not known to have financial backing or experience, and the contracts are being successfully completed. Low prices do not always come from big and successful contractors.

The speaker is in sympathy with a great many suggestions in this paper, but he believes that they apply largely to private work. Some of the recommendations made cannot be accomplished, especially on public works. For instance, contrary to Principle (5), the engineer cannot relieve surety companies on public works from giving a bond to pay for the labor and materials expended, because the statute laws of the United States and of some States require that such a bond must be given.

Principle (4) is a sound one. According to law, an owner may not specify the manner and method of doing the work and, at the same time, stipulate the materials to be used and then exact a warranty of results from the contractor. It is dangerous and productive of litigation to specify both how and of what materials the work shall be done and then say that the contractor "guarantees" or warrants it. The Court says that, if the structure leaks, although the contractor "warrants" it, he may not be held to the warranty. The speaker distinguishes between the words "guaranty"—which is a promise to pay the debt of another man—and "warranty"—which is a warrant of the work done and materials used.

The engineer usually prepares the "Information for Bidders". He makes soundings or borings; he determines quantities; the elevation of water surfaces or sub-strata; the character of excavations; the presence or absence of materials of construction, etc.; at great expense to the owner or municipality. Then what is done?

The contractor is told that nothing is definitely known about these quantities and conditions; that the owner will not be held liable; and that the contractor must be responsible for them. In a week or ten days he must get information that the engineers may have taken nine months to collect at a cost of thousands of dollars. That is a universal practice in advertising for bids, on either public or private work.

It is done to protect the owner from the possibility of adverse Court decisions if the judgment and knowledge of the engineer should prove to be inexact. As the author states, "nobody can see very far under water, or into

the earth"; but the engineer can judge better than the contractor. Owners may be sure, therefore, that the contractor will add to his price because of the repudiation of the engineer's estimate. (See Principle (3).)

The speaker suggests writing to 100 or 1 000 contractors and asking how much they would decrease their bids to a municipality if they had a positive declaration as to quantities and conditions existing on the proposed work and if they were not required to guess or take information from engineers only to have it later repudiated in the "Notice to Bidders".

To deny, or refuse, to support the engineer's report, is an act that deprives the owner or municipality of the money spent for engineering and investigation. The contractor must then be responsible for engineering data obtained by the owner, and he adds a liberal amount to his bid or contract price accordingly. In municipalities the practice has been promulgated by the legal departments in an effort to forestall or prevent successful litigation by the contractor.

The speaker has sometimes believed that the engineer quite approved the practice because it shifted the responsibility for errors in engineering work. The practice is justified by attorneys because when a contractor has obtained a large judgment against the owner, through engineering errors or misjudgment, it is a definite lump sum that is apparent and is felt by the defeated attorney; whereas the untold sums added by contractors to their bids are not so apparent. They are, nevertheless, met in even larger quantities by the owner or municipality.

The trouble with engineers is that they allow the lawyers to dictate to them what shall be included in the contract. Of what value is a report of investigations to contractors when the owner's lawyer (who prepares the contract) states that, in all events, the contractor shall be held responsible for the accuracy of the work of some one else?

The speaker believes that engineers do not realize how important the surety is to companies in the letting of contracts. The present tendency of corporations and municipalities is to make of the contractor a casualty insurance company by forcing him to indemnify the owner, not only for any negligence of himself or anybody that may act for him, but for anything at all that may happen—even under the direction of the engineer.

That is current practice in the City of New York. Where is there any justification for it? Again and again, the speaker has tried to have the legality of these clauses passed upon by the Court. State laws forbid anybody from writing insurance—casualty or otherwise—unless they are duly and properly authorized by the State and unless they accumulate and hold large bonuses. A contractor is not authorized to write insurance for the public or for municipalities, but the ordinary construction contract requires him to do just that very thing.

When confronted with this issue, judges of this State have avoided it by deciding the case on other grounds. Some day it will be decided definitely and, the speaker believes, that will stop the practice of requiring the contractor to act as an insurance company.

EDWARD W. STEARNS,\* M. A. M. Soc. C. E. (by letter).—There is so much that is good in this paper that it deserves careful reading by those whose duties include the preparation of plans and specifications for contract work. There are, however, a number of points included which, in the writer's opinion, are quite controversial and there is, furthermore, one very broad principle which is quite axiomatic and which deserves greater emphasis and amplification than was given it by Mr. Bush. The method of treating the subject adopted by the author is quite ideal and lends itself admirably to reading, discussion, and reference.

*Principle (1).*—Fundamentally, Principle (1) is correct, but its application should be followed with certain discretion. In the preparation of contracts and specifications it frequently happens that a broad general requirement, clearly and fully stated in its proper place, should be emphasized later by mention in special items subject to the requirement. When this is done, of course, it is of the utmost importance that each subsequent statement does not disagree in the slightest manner from the broad requirement first stated. No doubt a number of writers, and more particularly those of the legal profession, will take exception to this practice on the theory that by mention or emphasis of any particular application, the points not mentioned are, by inference, weakened if not entirely invalidated. In order to overcome this objection it is the writer's practice to include a clause of the following nature in the contract:

"The enumeration of particular instances in which the opinion, judgment, discretion, or determination of the Engineer shall control or in which work shall be performed to his satisfaction or to his inspection or of particular items to be performed without additional compensation, shall not imply that only the matters of a nature similar to those enumerated shall be so governed and performed, but without exception all work shall be so governed and so performed."

In the case of contract documents for a building, the broad requirement is laid down that the contractor shall comply with all Federal, State, and municipal laws and regulations and shall secure all necessary permits. These documents are prepared with the intention in mind that there will be a single general contractor on the work and that it is his obligation to comply with this provision. There will, however, be many sub-contractors engaged in the construction of the building, and in all likelihood the general contractor will expect each sub-contractor to comply with the laws prescribed and to secure such permits as are particularly required for his trade. It seems entirely proper, therefore, to indicate in the sections of the specifications pertaining to each trade, that the owner expects the contractor, meaning the general contractor, to see to it that all laws and regulations are complied with and that all necessary permits are secured, so that the sub-contractor shall be aware of the requirement and that he may determine his obligations from the general contractor.

*Principle (2).*—The writer desires to add to the discussion regarding Principle (2) a consideration of "cost plus" work. Many people engaged in con-

\* Asst. to Bridge Engr., The Port of New York Authority, New York, N. Y.

struction work seem to have little conception of the fact that a very important item in a contractor's cost is the question of overhead and that there is no fixed method among all contractors for the apportionment of overhead expenses. When the contractor is called upon to do work on the basis of cost plus percentage a definite agreement should be reached before any work is done, as to just how properly to compensate him for his overhead expenses and just how the item of cost will be measured.

It should be borne in mind that usually "extra work" is not undertaken because of the desire of the contractor for it, but because the owner finds it the most convenient way of handling certain minor matters. With this thought in mind it is only equitable that the contractor should receive not only his actual direct outlay in cash for labor and materials, but also both his overhead expense and a fair profit. By clearly understanding at the start just how the word, "cost", is to be defined, much controversy and ill feeling can be avoided and, as a result thereof, better work can be obtained due to a more sympathetic feeling between the contractor and the owner.

*Principle (6).*—Probably the greatest uncertainties which a contractor assumes in any construction work are those which are incident to foundation conditions. Those are the uncertainties which cannot be seen and must be felt. The writer thoroughly believes in sub-surface explorations, commensurate with the importance of the work involved, and believes further in furnishing to the bidder the complete information which he obtains from such explorations exactly as he receives it. It is obvious that his plans represent his interpretation of the results of such explorations. The writer does not believe in guaranteeing to the contractor either the correctness of the sub-surface explorations or that the conditions indicated by them will be found actually to exist; or, in other words, that the interpretation as indicated by the plans is correct. Those risks must and should be taken by the contractor.

As an example, the writer recalls a job on which extensive borings indicated a thick stratum of soft clay overlying a bed of gravel or hardpan. The plans required that the piers be supported on piles. After studying the samples from the borings, the contractor ordered piles of sufficient length to be driven through the clay and into the harder strata below, but in driving it was found that the piles would penetrate only partly into the clay. The cost of the pile cut-off was placed upon the contractor, the contract being a unit price job with a price per foot for piles driven. This ruling may seem to have been a hardship on the contractor. It should be borne in mind, however, that the full information furnished from the borings was in his possession at the time he prepared his bid, and, further, that he did not elect, before ordering his piles, to drive a few test piles by which he could have determined the probable penetration. Consequently, he assumed the full risk when he ordered the long piles and should not have been compensated for the loss incurred in the pile cut-offs.

The foregoing, however, does not, and in Court cannot be made to, hold if the sub-surface explorations are obviously insufficient or grossly incorrect. The writer recalls one job on which borings indicated rock at such an elevation

below water level that the excavation could presumably be done by the open coffer-dam method, and the contractor so calculated his bid. When the so-called rock was exposed, however, it developed that it was not bed-rock, but a rather unusual layer of large boulders. Subsequent exploration then revealed the fact that bed-rock lay at a depth so much greater than that originally contemplated that pneumatic caisson work became necessary. It is obvious that, to force the contractor to perform the pneumatic work at the price bid for coffer-dam work would have been inequitable, and could not have held in Court.

The foregoing should not apply to sub-surface man-made structures. The engineer should endeavor to determine to his best ability the existence, location, and character of all such structures and furnish such information to the contractor, thereby making him solely responsible. Should structures not shown on the plans be encountered, the risk thereof and any work involved in properly caring for them should be solely at the cost of the owner. As an example, on one job in the writer's experience there was encountered a 24-in., high-pressure water main which was not shown on the plans and which had to be moved. One entire section of the city was dependent almost wholly on this main for domestic use and fire protection. The removal of the main from the vicinity of the work was not an expensive operation, but the risk entailed was tremendous if the main had been broken or if a fire had occurred at the time necessary to shut off the water. Obviously, here the equity lay only in the owner assuming both the cost and the risk.

*Principle (7).*—The surety premium represents the charge for carrying certain risks. Obviously, then, if the risks are reduced the premium will be reduced and Principle (7) is only a statement of this fact in regard to particular risks. The writer believes, however, that the State lien laws are based on sound thought and, therefore, that the State and Government should provide the same protection as is given to the laborer or material man on private work. The risk for the payment of such claims is clearly one to be covered by insurance and, therefore, the surety should be required to guarantee the cost of unpaid labor and material bills.

*Principle (13).*—Except when there is no surety bond—and it is the writer's opinion that every contract should include a surety bond—the "retained percentage" is not withheld by the owner as a safeguard in case of default. On the contrary it is withheld for other purposes, as follows: (1) To cover incidental work of minor importance usually deferred until the end of the contract; (2) to serve as a liquid fund in case the contractor defaults; and (3) to act as a counter fund to offset any possible over-payment due to the approximate nature of the monthly estimates. Other reasons of lesser importance might be mentioned.

The writer believes that in the early stages of the contract the percentage which the "retained percentage" bears to the cost of work done, should be relatively high in order to build up a considerable cash fund, but that, as the work progresses and nears completion, both this percentage and the amount of the "retained percentage" should decrease until, when the work is entirely complete, they both should be relatively small. In one contract, the writer specified that 10% of the value of the work performed be withheld until such

a time as the retained amount equaled 5% of the total estimated contract price, after which time no further amount should be withheld. In another large contract he specified that until 25% of the work had been done, 10% should be withheld, after which the percentage was reduced on a sliding scale until, at the completion of the work, only 2½% was retained.

There is a feeling among many engineers and architects that a contract should be worded so as to force the contractor to finance himself very extensively. To this opinion the writer takes strong exception. He believes that monthly payments should be arranged so as to compensate the contractor as far as possible for the cost of the work as it proceeds. Usually this cannot be done in a simple way. In the early part of the work the contractor necessarily has a heavy investment and a relatively small amount of work performed so that his estimates do not and cannot fully compensate him. It is for this reason that his financial ability is important. After the work has progressed, however, if payments are properly arranged and if the retained percentage is not exorbitant, the time should quickly come when the payments should carry the contractor's cost.

Usually, the owner is in a much better position to secure the use of funds than the contractor. By compensating the contractor, fairly and reasonably, as the work progresses and reducing his necessity of obtaining loans, sometimes at quite high rates of interest, the owner establishes that feeling of good-will between himself and the contractor which is conducive not only to greater effort on the part of the latter to get his work done well and expeditiously, but also to cause him to reflect such feeling in his bid price. This is particularly true when the owner is in the market at more or less frequent intervals for construction work; but it is nevertheless also true when the owner is contemplating and planning only one piece of construction work, providing the contract and specifications are so worded as to show clearly to the bidder that he can expect fair treatment.

*Principle (17).*—It is with considerable humiliation as an engineer that the writer discusses this obvious principle. Unfortunately, the competition in engineering work has become so acute that the fees for it have become proportionately meager. Commercial organizations frequently seem to be so shortsighted as to consider the cost of the preparation of their drawings and contract documents as a whole as unproductive costs. This is fundamentally wrong. Care, thought, and study cost money, but when they are applied so as to produce drawings and contract documents that reduce to a minimum the points in which the contractor must use his imagination, the money so invested is saved many times over.

The engineer or the architect, whether he be employed as an outside agency or whether he be a regular employee of the owner on salary, has imposed upon him a great trust, namely, to construct for the owner, at the lowest possible cost, a structure which can best serve the owner's needs. Such results can only be obtained by the careful and thorough preparation of the drawings and contract documents. When he lends himself to any other practice on the grounds that he does not receive sufficient funds to justify such careful and

thorough preparation, the engineer or architect is breaking his trust most disgracefully and lowering the standard of the profession as a whole.

*Principle (21).*—The writer believes that it is best not to state the estimated cost of the work, even with limits as suggested by the author. The particular limits to be adopted would be subject to considerable variation in practice at different offices, and, if made broad enough to provide the possible range of price as found in bids for the majority of work, they would be of little value in indicating its size. A general statement of the approximate nature and dimensions of the work contemplated would seem to be a better basis for indicating its magnitude and character to the bidder.

*Principles (34), (35), and (36).*—It is essential for the writer to consider these three principles together. He takes issue with the author on four points, namely: (1) That the cash deposit required of the bidder is primarily required as a "bidding security"; (2) that it should be as much as 10 or 15% of the "probable contract price"; (3) that bid bonds are not desirable; and (4) that bid letters are not desirable.

The writer believes that the best bidding security is the bid bond or the agreement of proposed surety which is called a bid letter by the author. Since the responsibility of the surety, who must be acceptable to the owner, is apt to be greater than the responsibility of the bidder himself, in the writer's opinion the cash deposit at the time of submitting the bid has the chief purpose of giving a measure of the contractor's financial ability. Consequently, the amount of the bid deposit should be only sufficient to indicate that the bidder, if awarded the contract, has sufficient liquid capital or credit to proceed with his contract without embarrassment to the owner. Before awarding a contract the owner should require the contractor to submit an up-to-date financial statement. This, together with his bid deposit, should furnish the owner with sufficient information of the bidder's financial resources. It is difficult, if not impossible, to fix a formula for determining the amount of the bid deposit. It has been the writer's practice to fix it somewhere between 3 and 8% of the estimated cost of the work, depending on the class of work, the cost, and the length of time to be involved in completing it.

In conclusion, there is one broad principle applicable to the preparation of plans and contract documents which is axiomatic, but which nevertheless seems only too often to be entirely overlooked. Mr. Bush touched on it a number of times, but failed to emphasize it by setting it among his other principles. Briefly it may be stated as follows:

"Clarity and consistency are of prime importance".

Close attention should be paid to this principle, particularly in the preparation of the contract documents. Although, due to tradition and practice, certain legal phrases more or less difficult for the layman to read seem, by custom, to be unavoidable, the preparation of such documents nevertheless is only the practicable application of the English language. It is obvious of course that the individual preparing the contract documents must know what he wants and, to a certain extent, how to get it. Unfortunately, however, the documents are often so worded as to leave the contractor com-

pletely ignorant of the real intent. The point cannot be too strongly emphasized that every statement in such documents should be carefully weighed with a view to determining whether or not they correctly carry the thought which the writer desires to transmit. As a rule, the more brief and concise the documents are made, the more intelligible they are to those using them; but this consideration should not be carried to such an extreme that much is left to inference or interpretation.

Only too often, the writer fears, is it true that contract documents previously prepared—possibly even with careful analysis and study—are used as a guide in the preparation of subsequent documents. This practice often results in inconsistencies which are sometimes serious and many times quite ludicrous. The writer has had to review a specification prepared by another engineer, in which an entire chapter was devoted to a description of a type of work with which he was unfamiliar. Throughout the specifications reference was made to this work, thereby giving the impression that it was of considerable importance. At the first opportunity he questioned the man who prepared the specifications as to the details involved in this particular type of work, and after getting a reasonably clear conception of what was intended he inquired where it was to be used in the particular construction contemplated. Much to his surprise he discovered that none of it was contemplated, and the entire chapter and the references to it had merely been copied from a specification for an entirely different piece of work. Such practice is in much the same category as that of the calculator who claimed that he made only a very minor error in his calculation when he misplaced the decimal point. To some, the foregoing criticism may seem ridiculously obvious, but when one has encountered such conditions not occasionally but frequently over a period of years it becomes a very serious matter.

The preparation of drawings and contracts is only part of the story. After having attempted to emphasize the importance of fairness, clarity, and consistency in the wording and treatment of such documents a word to those whose duty it is to execute them and carry out their provisions is not remiss. In all the work that the writer has ever done he has made it an unvarying practice to convey to the contractor in one way or another the feeling that the contractor and the engineer are both working to the same end, with the same purposes in mind, and with the same obligations, namely, to complete the construction, whatever it may be, in the best possible manner, in the shortest space of time, and at the least possible expense both to the contractor and the owner with the intent of the plans and specifications and the purposes for which the structure is to be used. All the contract documents, therefore, become only a portrayal of the broad general principles under which the work is to be performed. It behooves the engineer in charge to establish with the contractor, by fair dealing, fair interpretation of the contract provision, and sympathetic consideration of the contractor's problems, that spirit of close co-operation and good will which alone will result to the best interests of the owner.

Too many engineers, from the lowliest inspector to the chief in charge of the work, seem to have the impression that the provisions on the contract

documents are immutable; that they must be followed to the very letter rather than to their intent; and that their prime obligation in carrying out the work is, if not completely to break the contractor, at least to see to it that he makes no profit. The contractor is entitled to a profit; to all the profit he can make, consistent with thorough and first-class workmanship. To deny him that profit by means of unfairly rigid and restrictive rules and by narrow-minded and short-sighted interpretations is the best way to create an unhappy condition in the execution of the work, a feeling of deep distrust and, in cases, even dishonesty on the part of the contractor, and, finally, expensive and uneconomical work.

RICHARD S. KIRBY,\* M. AM. SOC. C. E. (by letter).—The writer is in thorough accord with almost the entire paper. He has been struggling for years to inculcate just such principles into successive generations of engineering students. In his own mind he has classified Mr. Bush's "thirty-nine articles" into five groups, as follows:

(a).—More orderly arrangement of the material forming the contract documents: The writer suspects that much of the confusion to which the author properly calls attention has resulted either from leaning too confidently on precedent or from a division of responsibility in the preparation of the documents. Neither condition is typical of the engineer at his best.

(b).—A great degree of explicitness in the wording of the documents and in the data shown on the drawings, so as to remove uncertainties: To the writer's mind this group needs all possible emphasis, and Principle (3) is one of the most important of the entire thirty-nine, and the most difficult to put into practice. The writer would phrase Principle (9) differently—"Prepare each contract so carefully that nothing will remain for the Court to interpret." Courts and lawyers flourish on agreements entered into loosely. Construction work contracts ought to be so complete that if the contractor, owner, and engineer should die the day after a contract is signed, their successors would nevertheless find themselves in a position to carry out an agreement which did not lack precision at any point. The writer agrees especially with the suggestion that the graphic language be used in greater variety on plans. (See Principle (17).) Isometric drawings are so easily made and, at times, are so effective that it seems a shame that they are not used more often to supplement orthographic views.

(c).—More thorough and extensive engineering investigation of the project in advance: The writer agrees heartily with this general principle. He differs with Mr. Bush on Principle (27) only, as he can see no serious objection to percentage-unit bidding, provided the engineer gives proper thought to the preparation of his estimate.

(d).—Uniform treatment of bidders; improvements or changes in letting procedure: Doubtless the author had private, rather than public, work in mind in some of his suggestions; and it may be that architects are greater offenders than engineers in these respects. The writer questions the practicability of Principle (24) only.

\* Associate Prof. of Eng. Drawing, Sheffield Scientific School, Yale Univ., New Haven, Conn.

(e).—Reduction of sureties' duties, responsibilities, or liabilities: Some of this group of suggestions raises doubts in the writer's mind, especially Principle (39). It is plainly within the engineer's province to study carefully any matters concerning physical conditions relating to a project and to inquire into a contractor's reputation for good work, judged by past performances. How far an engineer should pose as a financial expert is another matter. Is not this plainly within the scope of the service which a surety company is expected to render?

J. E. Root,\* M. Am. Soc. C. E. (by letter).—This paper contains many points of active interest on the letting of contract work, and the relations between engineers, contractors, and surety companies.

*Preparation of Contract.*—The ideas presented in Section A cannot be emphasized too strongly. They practically cover the full field of controversy between the contractor and the owner or his representative, the engineer. The contract form should be brief, clear, and applicable to the work at hand; and, as an instrument, it should represent mutual regard for justice and fairness for each party to the contract. In construction, the instrument should be arranged in proper sequence, of general application, and should contain only matter relative to the particular case at hand. In brief, the one principle for the engineer to follow during its preparation, in order to fulfill completely the objective and purpose which the contract is to serve, should be to make it a logical, comprehensive, readable, reasonable, and workable form.

In the construction of a complicated piece of work the question of "changes" does arise. However, the contract form and the detail specifications need not, and should not, emphasize glaringly that the engineer reserves full authority to use the prerogative of continually harassing the contractor by making constant changes and modifications during the period of construction. The engineer's full responsibility exists during the time in which he is preparing the contract form, specifications, and plans. If, during this interim, he will give the same thought, care, and attention to the contract form, specifications, and plans, which he gives and exercises, in too many examples, after the award of the contract, a better workable understanding and a more harmonious working arrangement will exist between engineer and contractor. If the contractor is ordered by an engineer, or one of his subordinates, to make changes from day to day as the result of plans inadequately prepared, or to modify specifications not prepared to fit the work at hand, how is it possible for a contractor to organize his forces, follow a construction program, use his initiative and ingenuity in the execution of the work, or obtain in the end that to which contractors are entitled, a reasonable profit? The time for changes in the contract form, specifications, and plans is prior to advertising for bids, and the principle upon which engineers should work should be that no changes are to be made after the contract has been let. If they would adhere to this principle it would immediately establish a definite line of demarcation between the engineer's functions and the contractor's functions during the life of the contract.

\* Special Engr., The Cincinnati Union Terminal Co., Cincinnati, Ohio.

Small scale drawings bound with the contract document serve no useful purpose. If it is necessary for the engineer to depict the work to himself by large scale drawings and to correlate all features and details of the problem by various suitable scales, it cannot be presumed that small scale drawings will give full information and enlightenment to a contractor or his engineer representative. The legal connection between the drawings and the contract, can be established by direct written reference made in the contract or in the specifications.

The defaults by contractors are usually from one or a combination of the following causes: (1) Lack of experience or financial responsibility; (2) bid prices that do not represent the actual cost, plus a reasonable percentage for its execution; (3) continued interruption and interference on the part of the engineer; and (4) contingencies arising during the work, which are beyond reasonable expectations.

To meet the first and second anticipated possibilities it is incumbent on contractors themselves to use judgment and discretion in bidding on proposed work. Contractors as well as engineers obtain experience gradually by their increased initiative and desire to expand a little at a time from a moderate to an involved class of work. In time, contractors as well as engineers, establish for themselves a classification and should only be encouraged to compete for work of a class in which they have clearly demonstrated that their past ability will fairly represent the probable successful execution of the work at hand. On this basis it is immaterial whether a 10% or a 5% retainer is withheld for the owner's protection against possible default, because, when expressed in a percentage of the contract, it represents in part the item of profit to the contractor. Carefully prepared balanced bids usually provide adequate funds to meet current obligations and a continuation of the necessary banking credit. The third and fourth possibilities speak sufficiently for themselves.

Established custom may easily and conveniently be modified so as to provide protection for the contractor against the possibility of changes in plans made by an unscrupulous engineer. For example, all bidders should be allowed to retain the plans until ten days after the award and the successful contractor should be permitted to keep, as his personal property, the plans used to prepare his bid. All deposits made for securing the plans could then be returned, or disposed of as the instructions to bidders may provide.

Usually, the period between the advertisement for bids and the date upon which they are to be submitted is too short to give a reliable contractor sufficient time for a just and careful consideration of the work involved. After the completion of plans and specifications that have taken months and sometimes years to prepare, engineers are, as a rule, entirely too anxious to receive bids and get a contractor started on the execution of the work. This time period should be reasonable and should vary with the class of work on which bids are to be obtained.

*Section B.*—Under the caption, "Advertisement for Bidders", there is one humiliating feature that the author has failed to mention. Too fre-

quently the notice for a letting is advertised in an engineering magazine of general circulation and it contains each and all of the points mentioned as being of interest to contractors. The result is that "out-of-town" contractors respond. They spend their time and money obtaining information and then submit a proposal which is sometimes the lowest bid. It is not a mere circumstance, nor is it evidence of fair dealing, when the low bidder is informed that "the work has been given to a local contractor". Under those circumstances, the engineer should withhold the advertisement from engineering magazines, and should state in the "Instructions to Bidders" that the contract will only be awarded to a local contractor.

*Information for Bidders.*—To obtain fair and equal competition between contractors, full and equal information should be given by the engineer to each and every interested contractor. Too many engineers have favorites. As a rule contractors are less "hidebound" than engineers, and they respond very quickly to fair and honest dealing.

On public work it is usually one of the regular requirements for the engineer to prepare an estimate in detail, and for private work it certainly has been prepared for the benefit and information of the owner. A responsible contractor obtaining the details contained in this estimate will not be governed or controlled thereby in his judgment as to bid prices. If the engineer is fairly competent to prepare the plans and specifications, he is the one most competent to portray the work involved on the plans by his estimate as to quantities, and this is the part of the detailed estimate in which responsible contractors are most interested.

A reasonable period of time between the date of the award of the contract and the date when actual work must be started by the successful contractor should be given. Involved estimates which have taken the engineer a long time to prepare generally also require at least a reasonable period of time on the part of the contractor before he can complete his negotiations with material and equipment dealers, sub-contractors, etc.

*Awarding the Contract.*—Bids for public as well as private work should be opened publicly and read. Secrecy plays no part in fair dealing or in the creation of an agreeable, straightforward, working relationship between engineer and contractor.

Certainly, in fairness to those who may be equally qualified by experience and financial responsibility, the contract should be awarded to the lowest bidder. Furthermore, when alternate items are included on the plans and in the proposal, the work should be awarded on the basis of the lowest alternate. When alternates are specified by the engineer, it is to be presumed, and should be only so considered, that each and all of them are equally adaptable for the work to be constructed. If this is not the case the engineer should declare himself clearly so as to avoid misleading the contractor and exciting the hostility of those directly interested in the alternate.

SPENCER A. SNOOK,\* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is timely and brings attention to carelessly worded specifications and to plans

---

\* Bridge Designer, State Highway Dept., Jersey City, N. J.

insufficiently detailed and designed. It also directs thought to the relation of surety bonds to contracts. It is desirable to have the honest co-operation of all parties and the co-ordination of all the factors involved.

The writer believes that, in the majority of cases, the unit price bid is the best for all concerned. Changes which involve more than a simple reasonable increase or decrease of any item bid are sometimes necessary in the contract. Such changes are, or should be, beyond the control of the owner's engineer because of conditions not possible to foresee. Changes other than these should not be necessary, because plenty of time should be given to study the design, to prepare the drawings in sufficient detail, and to obtain the best borings and other sub-surface information. The engineer does not always have sufficient time to make complete plans; he is often forced to get them done within a certain time limit. Some engineers do not think it necessary to go into details, because they know that those who prepare shop drawings like plenty of leeway. This is a viewpoint that is favored altogether too much. With detailed plans available, the checking of shop drawings is made easier and quicker and the engineer is more likely to get what he really wants. Furthermore, engineers who know how to make plans with enough details will not do that work for the money customarily offered. It is the same old story—"if you want something good you must pay for it".

The specifications cannot be written too clearly and too concisely. Provision should be made for supplementary written agreements between the contracting parties for necessary and unusual changes. A description of the work to be done and possible obstacles to be overcome should be stated plainly.

To demand good workmanship alone might lead to considerable argument. If good results are specified, only good workmanship will produce them, generally speaking. However, when certain methods produce the good results desired, it seems best to call for those methods to be used, because the results otherwise may be considered good, but not just what was wanted. Also, it is important, very often, to call for materials of a certain kind, especially for concrete of a certain strength, or structural steel, bearings, etc., of a certain make, since good results cannot be judged by visual inspection.

The quantities bid upon should be calculated accurately to the best of the engineer's ability and information, since he knows the construction involved. The bidder should be furnished with all known information and requirements, and anything that is not positively known to be accurate should be so marked.

It would seem fair to ask the contractor to guarantee the work done under his control by means of a surety bond. There are some owners who may not know when a bid is too low or that the contractor is not a responsible one. Such people need some form of protection and for them a surety bond is desirable. The surety bond should be regarded as a guaranty against claims and damages and for the prompt execution of the work with the results specified, as all are within the contractor's control. If the owner never had any worries about these things, he would not require a contractor to obtain a surety bond. There must be some risk whenever a surety bond exists with a contract. The amount of that risk to be taken, respecting the responsibility of the contractor to pay for his labor and materials and to finish the work as desired, is something for

the surety company to decide when writing its policy. If it takes good risks, the premiums should be low, but if it just wants to sell policies without knowing how responsible the contractor is, the premiums will be necessarily high.

Cash, or the bidder's check for bidding, is preferable to bid bonds. The acceptance of letters which guarantee a bond to the successful bidder is an undesirable practice and should be eliminated because of the possibility of collusion.

It might be well to keep the surety company advised on monthly estimates and changes in contract, having in view the ratio of work completed to that to be done within the given time limit.

J. A. LENECEK,\* M. Am. Soc. C. E. (by letter).—The author has done a great service by offering a list of suggestions of a very practical value. It is regrettable, however, that this admirable paper suffers somewhat from the author's occasional criticism of the engineer's work through the different phases of competitive bidding. Sometimes these critical observations are self-contradictory.

For instance, the author admits that "nobody can see very far under water, or into the earth", but, later, he seems to forget that the word "nobody" should impartially include not only the contractor but the engineer as well. This inconsistency is apparent when the author suggests that the engineer should remove all uncertainties from sub-surface work, in advance of receiving bids. According to current practice the engineer supplies the bidder with all the necessary field facts (borings, soundings, etc.) and from these the contractor draws his own conclusion about the probable risk of the proposed work. No doubt an uncertainty always will exist if such field facts are not correctly interpreted by the bidder; but for such a condition the contractor should blame only himself, because it is primarily his affair to know his business. He should not expect any help from the engineer, who is usually busy in his own field. As a matter of fact the competent contractor knows how to analyze his costs correctly, while the inexperienced bidder, as a rule, estimates the risk too highly and on account of his high bid eliminates himself, which is a wholesome condition for the owner.

The author suggests a very good method of testing the bidder's financial responsibility, but it hardly offers any hint of how to test the contractor's competency. Perhaps the author also subscribes to the prevalent idea that a financially responsible contractor is in a position to acquire satisfactory plant and a good organization; however, money cannot buy successful experience and a good reputation.

In Spanish-American countries as well as in certain countries of Continental Europe, it is quite customary to subject the bidders on public work to a competency test. For this purpose a careful engineer's estimate is secretly prepared. Measures are also taken to prevent any information concerning the work from reaching the prospective bidders. To that end the chief engineer of the main Office for Public Works selects a few of his widely separated district offices and assigns to each office the preparation of a certain part of

\* Section Engr., Board of Transportation, New York, N. Y.

the engineer's estimate. The selection and assignments are known only to the chief engineer. Each district office presents its completed work in sealed envelopes at the public hearing held for the opening of the submitted bids. At this meeting all bids are tabulated. Later, the engineer's estimate is compiled from the sealed envelopes, and finally the successful bidder is selected. His detailed computations then must be submitted.

The fortunate bidder is picked out in a manner quite different from general practice in the United States. The lowest bidder is not chosen, necessarily, but the one whose bid is numerically closest to the engineer's estimate. It is contended that by this method the contractor demonstrates the reliability of his experience and his organization and that he is qualified therefore to do the work. The bidder is also required to prove his financial responsibility. The writer has had an opportunity to observe that the entire system "works" remarkably well.

JACOB S. LANGTHORN,\* M. A. M. Soc. C. E. (by letter).—The author's long experience in the surety phase of contracting has enabled him to produce a very useful paper on the business side of engineering. A development of similar interest is the formation in 1927 of a Board of Reference in the City of Boston, Mass. This body is composed of twelve members, five selected by the Boston Society of Architects, five by the Boston Building Congress, and two by the Boston Society of Civil Engineers. It is aimed specifically to meet some of the injustices mentioned in the paper.

In service, the Board comes into operation in case a contractor finds items in plans or specifications that seem unfair or inadequate. He then refers the question confidentially to the Board before the competitive bids are submitted. The Board on its part will pass on the criticism and, if justified, will refer the question to the author of the plans and specifications. He, in turn, may answer the criticisms satisfactorily; otherwise, he will be asked to amend the forms or issue additional explanatory information to cover the omissions or defects. If time does not permit this, he may give assurance of future correction of defects. In case no agreement is reached, the Board will file formal reports with the three bodies from which it is formed. Such cases will constitute the basis for revisions in the Code of Practice which the organizations will be asked to approve. It is to be noted that there is no intention of acting in any way after contracts are once made.

As to Principle (9), it is exceedingly useful to have the date that a blue print is made shown on each copy. Especially is this important in building construction where the architect's tracings are made in pencil. Without the date it becomes difficult to establish priority.

In connection with Principle (14), one surety company to the writer's knowledge sends periodically a blank form following up work for which it has issued bonds. While the form does not require the complete monthly estimate, it does call for essential information as to the progress, percentage completed, and amount paid to contractor.

With Principle (29) there is a discussion of returning all documents with the bids. This practice is followed by many architects in New York

\* Cons. Engr., Office of Borough Pres. of Manhattan, New York, N. Y.

City, but is manifestly unfair, as a contractor is entitled to retain the specifications and drawings upon which he has bid until his bid has been rejected.

EDWARD W. BUSH,\* M. Am. Soc. C. E. (by letter).—When preparing this paper the writer was frequently puzzled to know which points to include and which to omit. The general subject is broad and many important matters would have been included if the paper already had not stretched itself to a considerable length. Most of the topics are those on which the writer's experience indicated that changes could be made in the average current practice with economic advantages to the construction industry. A few subjects were included that, it is thought, would be of interest in the present-day discussion on the pre-qualification of bidders, the determination of the responsibility of a contractor, etc. These topics are closely interwoven in the general subject.

A few of the discussers have stated that the paper represented the viewpoint of the surety, but the writer disavows this and wishes it to be considered as the effort of an engineer who is drawing on many years of professional experience acquired before becoming connected with a surety company, as well as the experience gained after such connection was made. Some of the arguments and principles offered are adverse to what might be termed the best financial interests of the sureties.

The writer greatly appreciates the discussions offered. Many of them add supplemental material of distinct value, and all of them are of interest because they reflect the ideas of different persons variously engaged in the industry. Existing statutes will prevent the adoption at certain places of some of the principles even if they may be thought desirable and there will be many cases in which some of them are either not needed or inapplicable. A few of the discussions explain special conditions under which certain principles do not apply.

Mr. Wason points out that small scale drawings referred to in Principle (11) would be expensive and unsatisfactory, while photostatic reproductions would be simple and inexpensive. The writer termed them "reduced scale copies of the drawings" and had in mind the regular drawings reduced by some photographic process as is frequently done when they are bound with the contract.

In regard to Principle (12) Mr. Wason states that quantity surveys of this kind are sometimes used to adjust extras instead of merely as the basis for progress payments and such a use may do a rank injustice because the data may have been unbalanced. Whenever a contractor unbalances either a unit price bid or a schedule of the kind here considered, he takes a chance that later may work against him.

If the owner states in the contract (in accordance with the usual practice) that a certain percentage will be withheld from the progress payments, it is important to the owner that he observe this provision strictly and that he does not overpay the contractor at any time. Otherwise, he may be compelled to replenish the fund to the extent of the over-payment, for the benefit of those having lienable claims. Whether the method of paying for floor by floor, etc., suggested by Mr. Wason, is feasible without over-payment

\* Engr., Aetna Casualty & Surety Co., Hartford, Conn.

depends on the way the amounts are predetermined. Certainly, it is an easy way to handle a problem which, in the past, has been the subject of many acrimonious disputes between contractors and owners.

Principle (26) states that bids should be disposed of within thirty days after they are received. Of course, it would be desirable if this period were reduced to the ten days offered by Mr. Wason, but some public-work bodies meet only once a month; then, also, some time is frequently needed in which to finance a proposed construction. Therefore, thirty days were offered more as an outside figure than as a practice to be followed generally. The main thing is to state a time limit and to make this as short as possible.

Mr. Rudolph mentions the quantity-estimating agencies at various locations that now offer estimates to contractors and owners, and states that the engineer or architect who prepares the plans is better qualified to furnish such quantities than outsiders. Principle (28) suggesting quantity surveys applies only to building work and the writer had in mind quantity surveys of the kind offered by the owners in England. For some unknown reason the architects of the United States have never shown any enthusiasm for the English practice although contractors have many times pointed out to the owner the economic advantages if this practice were to become established. Engineers follow the practice every time a unit price contract is offered to bidders with the estimated quantities included. It is believed that the independent estimating agencies now operating in this country are the outgrowth of the efforts of groups of contractors to have joint or co-operative estimates prepared for them. A considerable volume of this quantity survey work is now being done—much more, perhaps, than many realize—and, of course, this labor really is being paid for by the owners. The writer agrees with Mr. Rudolph that this estimating can best be done, or at least supervised, by the architects who prepare the plans. If the volume increases and the agencies multiply, the architects, no doubt, finally will consider that quantity surveys are of some economic advantage and that their preparation is a matter to be supervised by them.

Mr. Wait's remarks are of especial interest as they are from a man who is broadly experienced in unraveling construction tangles. He questions, however, the value of the pre-qualification of bidders as to adequate financial strength and experience when he states that there are others not so fortunate nor successful who can carry out the contract, and that some of the biggest public works built to-day are by contractors who were not known to have financial backing or experience. Now and then one hears it said that "any contractor can get a bond no matter how weak financially, or inexperienced." Those behind the scenes, as it were, in the surety business know that such a statement is not true, and surety bonds on important contracts are not issued on behalf of inexperienced or financially weak contractors. Mr. Wait, perhaps inadvertently, gives the information that will reconcile his statement with the one just made by the writer when he says that "contractors who were not known to have financial backing" are able to handle large public work contracts successfully. No doubt, these contractors obtained surety

bonds as public work was mentioned and if they were financially weak the sureties did not issue the bonds until after additional financial strength was put in the organizations. In most such cases, which are of common occurrence in surety underwriting, the fact that additional strength was put in is known to only the contractors, the sureties, and those supplying it. This is why some apparently weak contractors are able to obtain contract bonds.

Mr. Wait makes a valuable contribution to the paper when commenting on the absurdity of making the contractor assume the risk of the accuracy of the engineer's preliminary investigations of the site—work which may have cost a large sum. His remarks on the manner in which engineers allow lawyers to dictate what shall be put in the contract, are certainly refreshing.

Mr. White, in discussing Principle (13), questions the necessity for the owner to withhold a percentage of progress payments made to the contractor when the owner already has the protection of a contract bond guaranteeing the completion of the project. It is true that the bond extends this protection to the owner, but the present bond premium charges are based on the assumption that the customary 10 to 15% will be retained by the owner and if future practice materially reduces the retainage or discontinues it there is every probability that premium charges on contract bonds will be increased. There is a considerable volume of private work on which no bonds are required and the owners in such cases certainly need the protection of retainages.

The retainage often furnishes a good reason why the contractor rushes a job to completion and while it might be advantageous to the owner and the contractor in some cases to make all progress payments in full, it is believed that the time-honored custom of retaining from 10 to 15% is one that is generally desirable. A stipulation of full payments would require the monthly estimates to be made much more carefully than under the present practice of making approximate estimates when a retainage is withheld; and as the retainage is something earned by the contractor he can generally borrow against it if he needs the funds. In certain localities the owners permit the contractors to convert the retainage into high-class interest-bearing securities which are held by the owners, and this privilege has much to commend it.

Colonel Waldron, apparently, takes the position that the more the engineer tells the contractor in advance of bidding the higher the bids will be. He states that "when the contractor knows all hazards to be encountered, he is apt to bid higher than if he has to take a chance here and there." This assumes that the contractor is a rather stupid fellow who has to be told about a hazard in order to recognize it. It is believed that most present-day contractors are fully competent to recognize quickly the hazards and to bid accordingly. If they are not competent to do this, they do not remain long in the business of contracting. Principles (8), (6), and (25), with the supporting arguments, were offered in the paper with the hope that they would show that it is to the economic advantage of the owner to remove uncertainties if possible before offering work for bidding. As far as any interest of the surety on these points is concerned, it is well to keep in mind

that the surety does not begin to pay on a claim until after the contractor has spent or pledged all he possesses. The contractor becomes a poor risk for himself before he is a poor risk for his surety.

Mr. White presents the contractor "as a human being entitled to justice" and points out that even after some of the uncertainties are removed the contractor has a strong economic factor to evaluate and a big risk to carry when he is engaged on contract work. In antithesis to this, Colonel Waldron states in the usual procedure "the engineer tries to get as much as he can for his employer; the contractor tries to do as little as possible in order to increase his earnings". The writer believes that most engineers and architects are fair-minded, with no desire to "put over" anything on a contractor; and, also, that most of the present-day contractors desire to perform their contracts fully. According to current business ethics it is poor policy for either to do the contrary. The greater proportion of all the construction work done in this country is in the hands of members of the Society, which will not knowingly admit a "crook", be he a contractor or an engineer.

Mr. Bernstein presents an interesting fact when he states that at times contractors on private work are compelled to accept paper in lieu of cash because the owners have failed to finance the undertakings completely. The writer has seen many financial statements of contractors showing large "accounts receivable" items which were uncollectable because the owners could not pay them. This is more apt to happen to a young contractor than to an experienced one because probably the latter has been caught, or is afraid he might be caught, in this way, and has learned to avoid such pitfalls. A somewhat similar topic was presented in the paper under the caption, "Introductory" and was mentioned in the paragraph preceding Principle (6).

In commenting on Principles (17) and (25), Mr. Bernstein points out that frequently the engineer lacks sufficient time to prepare complete drawings, etc., but that when sufficient time is available there is little cause for complaint. The observations of the writer, after being in a position to note this point on hundreds if not thousands of cases, leads him to state that there is room, when full time is available, for considerable improvement in the current practice on these details.

Mr. Stearns discusses many parts of the paper in an interesting and constructive way, but some comments on his discussion are needed. He mentions the advantage of the repetition in the contract documents of a subject like the provision that the general and all sub-contractors must obtain permits, etc. If Principle (11) is observed, the general conditions of a building contract always will be attached to the specifications of any particular trade and a requirement once expressed will apply to all trades.

In supporting his statement that certain "risks must and should be taken by the contractor", Mr. Stearns mentions a case in which longer piles were ordered than could be driven and as the number of linear feet driven was the item paid for, the cost of the extra lengths was borne by the contractor. This example is exactly of the kind the writer had in mind

when writing Principles (3) and (6). In line with these principles, the owner in the example just mentioned would obtain more economic bids by dividing the pile work into two items, one covering the lengths delivered, and the other the lengths remaining below cut-off; also, by sub-dividing the first item and asking for bids on different probable lengths that will be required. In applying this scheme the engineer and contractor should confer on the probable lengths needed before the piling is ordered; then the contractor can prepare his bid with a reasonable assurance that he will not run into some unknown bottom condition that will cause him a loss and, therefore, can bid closely without a considerable factor added for the unknown. The writer has used this method of buying pile foundations and knows it to be successful.

Principles (7) and (8) were included by the writer because they are germane to Principles (18) and (19), and also because in recent years the industry has been offered some discussions on bonds which have overlooked many of the points mentioned in the paper. Mr. Stearns is correct in declaring that Principle (7) is a mere statement of fact—a fact that many States have overlooked when seeking to reduce the cost of contract bonds.

Regarding retainage mentioned by Mr. Stearns, the writer believes Principle (13) is true irrespective of whether or not a surety protection is obtained by the owner. Many border-line cases would not have been bonded by sureties if no retainages were held by the owners.

The writer fails to understand why an engineer or architect is frequently so reluctant to give the prospective bidder some idea in the advertisement as to the probable bid price. The engineer would tell the bidder verbally when he is starting his investigation or he would tell newspaper reporters preparing an article on the improvement. The bidder knows the size of job that will fit his organization and nobody is benefited when he bids against his best interests. Why lead him to investigate a \$100 000 job when he is looking for one of \$500 000, or *vice versa*? The sureties are constantly receiving many preliminary guesses on probable bid prices that are from 50 to 100% in error. Such guesses are disturbing factors in underwriting border-line contract bond cases and have caused much "grief" to both contractors and their sureties. The easy and obvious way is to tell the prospective bidder at the start the approximate price of the contract offered for bids.

Mr. Stearns does not believe the "bidding security" is in fact what the words imply. In nearly every case the contract documents precisely state the conditions under which the security is deposited—that it is a guaranty the contract will be executed, etc., if the bidder is awarded the contract. If the owner feels that he needs a "bidding security" he should get it large enough to cover the probable difference or spread between the bid that is accepted and the next higher even when these two bids are somewhat out of line. Taking Mr. Stearns' viewpoint of the matter, the 3 to 8% mentioned by him is not large enough to show sufficient working capital to finance the job and absorb an ordinary loss, especially as the contractor may have other contracts under way or may take subsequent contracts.

The writer is very much in accord with the closing paragraphs of Mr. Stearns' discussion and believes the paper could have included with propriety another principle on clarity and consistency. Many forms plainly show the confusion brought about from the "scissors and paste-pot" method of preparing them. The writer recalls a contract and specifications wherein the parties of the first and second part mentioned in the contract were transposed in the specifications so that among other things the owner was obligated to pay the contractor \$25 per day for any delay in completing the contract beyond the date set.

Mr. Consoer offers many valuable suggestions among which are some on specific data that should be given to prospective bidders, which are in general agreement with Principles (3), (6), (17), (21), and (25). His practice of giving bidders a copy of the "Instructions to Inspectors" no doubt has prevented many disputes during the construction period and is one that could be followed with advantage to all parties.

Mr. Stephenson refers to Principle (21) and discusses whether or not an approximate estimate of the probable bid price, within limits, should be included in the advertisement. In connection with the "spread" between the high and low bids on an ordinary class of work and in cases where the highest bid is perhaps 50% greater than the lowest, the writer has generally considered that the top one-third or one-half of the bidders really did not expect to obtain the job but merely wanted to take it at very attractive prices. The discussion preceding Principle (30) considers this class of complimentary bidders and the disturbances they sometimes cause. Of the remaining bidders, a check-up of the volume of other work on hand, the financial condition, the previous experience on similar work, and whether or not new plant must be purchased and additional organization secured by the respective bidders, will show which of them really bid closely to obtain the job. In general, it is the bottom one-third of the bidders who, perhaps, are best equipped, who need the work, and are seriously competing for it. There is a variation to this that occurs now and then, wherein the talented contractors—those who really know what the job is worth—are found grouped considerably above the lowest bidders and it is evident that the latter are inexperienced and have made a sorry mess in their estimation of the price. Still another variation is that of the very capable contractor who, apparently, bid so far below the others that he faces a loss, but who at completion retains a fine profit after having given the owner a good job.

Professor Kirby offers a good summary of the general subject treated by the paper. His comment on Principle (39) questions whether the engineer should go far into the analysis of the contractor's financial condition, stating that this, perhaps, is within the scope of the surety's service. On work which is not bonded the engineer or architect will probably make the analysis if one is made, but on bonded work the surety will make the analysis, not as a service to the owner, but for its own protection. The writer included Principle (39) and its argument because they set forth briefly the methods of the sureties in determining the responsibility of contractors, and it was thought that this

information would interest engineers and architects, especially in connection with the awarding of contracts that would not be bonded.

Mr. Root contributes an admirable discussion. The writer is in general accord with him and will only comment on one point. He states that small scale (reduced scale) drawings, bound with the contract, serve no useful purpose. The writer has reviewed a large number of cases in which the contract drawings, evidently reduced by a photographic process, were either bound with the contract or placed in an envelope attached to the back cover of the volume, and in no case has there been any uncertainty as to the details shown. Some of these jobs, running into millions, have been of large dams, bridge foundations, conduits, sewers, etc. The method will operate better with engineering than with architectural constructions, and the writer believes that if once tried the engineer will continue to use it on future work, if possible.

In the statement that "nobody can see very far under water, or into the earth", the writer attempted to epitomize many reasons why changes will be made in contracts after they are signed. The writer fully agrees with Mr. Lenecek that "nobody" includes the engineer as well as the contractor, but the writer does not recall that the suggestion is made anywhere in the paper that "the engineer should remove all uncertainties from sub-surface work". In Principle (3) and elsewhere the writer offers the thought that the more the uncertainties are removed, the lower will be the bids, which is quite different. Risks are inherent in certain kinds of work, but every time one of them is removed in advance of the bidding the price is lowered.

Mr. Lenecek states that the writer hardly offers any hint as to how to test the contractor's competency although a way to test his financial responsibility is given. In the discussion preceding Principle (39) the writer uses the word, "responsibility", as including, among other qualities, the financial strength and competency. To be responsible the writer states that in addition to being honest the contractor "should have ability as evidenced by his past experience and record; an organization suitable for the proposed work; and sufficient working capital or net quick assets to finance the operations and reasonable additional costs". Principle (33) refers to questionnaires and the footnote under "Introductory" mentions the "Standard Questionnaires" which were printed in the March, 1926, *Proceedings* of the Society. The writer knows of no working formula worthy of consideration that could be applied to the information secured on a contractor's past experience, etc., that would determine his competency. The matter, except that of financial strength, is one of individual judgment, because so many of the qualities, while capable of being recognized, cannot be evaluated. No two engineers or architects will give the same weight to the information, although it is to be expected that experienced engineers, architects, and surety underwriters will be found in fairly close agreement on an analysis of the kind of data herein considered.

The writer touches on a legal question here and there in the paper and wishes to state that all these points were checked by consultation with eminent legal counsel broadly experienced in the subject matter.

Paper No. 1741

### SPECIFICATIONS FOR TRANSIT TRAVERSING AND STADIA LEVELING\*

By W. H. RAYNER,† Assoc. M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. C. V. HODGSON, C. KELSEY MATHEWS,  
HOWARD S. RAPPELVEY, AND W. H. RAYNER.

#### SYNOPSIS

This paper has for its purpose a consideration of the effect of the errors in combination which attend the work of transit traversing and stadia leveling. It indicates a method whereby specifications for each operation in the field work may be prepared, so that the survey as a whole may be most economically and expeditiously executed.

The theory of errors has been adequately developed elsewhere, but for the most part, it has been applied to measures of precision, such as the probable error, and others, and to the adjustment of observations by the method of least squares. Authors of textbooks treat the various sources of error separately, but the total effect of the errors in combination in the surveying processes, appears to have received but little consideration. This is especially true as regards surveys of ordinary or low precision.

Many surveys are so simple in plan and are of such small scope that any detailed analysis of the methods would be absurd, but it has been the writer's observation that engineers who deal with surveys only occasionally, are apt to use about the same procedure and precision for one and all alike, with the result that on work of any magnitude or importance much time is wasted, either in unnecessarily refined measurements or in repeating the measurements to achieve satisfactory results.

It may be added that this paper is intended to indicate a method only, and is not a complete treatment of the subject. Many sources of error that

\* Published in December, 1928, *Proceedings*.

† Asst. Prof. of Surveying, Univ. of Illinois, Urbana, Ill.

are not mentioned will be found important under certain field conditions; but the method indicated herein should enable the engineer to specify intelligently—for any survey and under any conditions—the care which should be used for each part of the field work.

#### DEFINITIONS

In the usual treatment of "systematic errors" it is assumed that, in some cases, their effect can be eliminated either by corrections applied to the measured quantity, or by systematic field methods. Thus, it is stated, the effect of the incorrect length of tape can be corrected by a computation, or the effect of non-parallelism between the axis of the level tube and the line of sight in an engineer's level may be eliminated by taking foresights and backsights of equal length. In this paper, however, a fundamental conception is that an error always is a quantity of which both the magnitude and the sign are unknown. Accordingly, in so far as the conditions mentioned do not affect final results, they are not considered as errors. In accordance with this conception, the following definitions are given.

*A Systematic Error.*—An error which always has the same (unknown) sign, and, therefore, is cumulative in its effect—but the magnitude of which cannot be calculated—is a systematic error. Its effect cannot be removed by systematic field methods.

*Accidental Errors.*—Such errors have the following characteristics (assuming that a large number of observations are taken): (a) Plus and minus errors are equally numerous; (b) small errors are more numerous than large ones; and (c) very large errors do not occur.

*A Cumulate.*—That part of the effect of a source of error which can always be eliminated either by a computation, or by a systematic field method, is termed a cumulate.

*Mistakes.*—Differences from true values, arising from confusion in the mind of the observer, are mistakes. They are detected by checking the work and are eliminated by applying corrections. It need not be added that the subject of mistakes has no place in a discussion of errors.

*The Probable Error.*—This is an error of such magnitude that in a series of like measurements, the number of errors larger, equals the number of errors smaller, than the probable error. In other words, in a series of like measurements, the probable error has such a value that the chances are even that the error in any single measurement, taken at random, is smaller (or larger) than the probable error.

These definitions are made clearer by the following examples.

*Example 1.*—Let it be supposed that a steel tape is to be used in a careful survey. It is sent to the U. S. Bureau of Standards, Washington, D. C., where its length is determined to be  $100.021 \pm x$  ft. In using the tape its length is assumed to be 100.000 ft. Hence, the quantity, 0.021, is the cumulate and the quantity,  $\pm x$ , is the systematic error. In the process of chaining, the small errors made in marking the ends of the tape are accidental errors; and a mistake would be made if a fractional distance of 59.13 ft. was misread as 61.13 ft.

*Example 2.*—A level party is required to carry a line of levels across a river. The levelman reads a rod held on a bench-mark on the near bank of the river (B. M.<sub>1</sub>), as  $4.37 \pm x$  ft., and on the far bank (B. M.<sub>2</sub>) as  $8.31 \pm y$  ft., from which the difference in elevation is determined as 3.94 ft. He calculates the effect of curvature and refraction to be 0.04 ft. This is subtracted from the reading on B. M.<sub>2</sub> and the corrected difference in elevation is determined as 3.90 ft. In this case the quantity, 0.04 ft., is a cumulate;  $\pm x$  and  $\pm y$  are differences from true values affected by both kinds of errors: (1) The accidental errors arising from such causes as leveling the instrument, sighting, holding the rod, etc.; and (2) the systematic error due to the imperfect adjustment of the instrument.

#### THEORY OF ERRORS AND THE INTER-RELATION OF ERRORS

No attempt is made in this paper to derive the fundamental formulas.

*Compensation.*—This principle states that in a series of observations affected by an accidental error the total probable error is given by the product of the error in a single observation times the square root of the number of observations. Thus,

$$E_T = E_s \sqrt{n} \dots \dots \dots (1)$$

in which,  $E_T$  is the total probable error;  $E_s$  is the probable error of a single observation; and  $n$  is the number of observations in the series.

*The Summation of Errors.*—This principle states that if the total probable error of a measurement is the result of several errors acting independently, the value of the total probable error is given by the square root of the sum of the squares of the separate probable errors arising from the several sources. Thus,

$$E_T = \sqrt{E_1^2 + E_2^2 + E_3^2 + \dots E_n^2} \dots \dots \dots (2)$$

in which,  $E_T$  is the total probable error, and  $E_1, E_2$ , etc., are the separate probable errors affecting the measurement independently.

*The Product of Errors.*—If a measured quantity,  $x$ , is the result of two independently measured quantities,  $A_1, A_2$ , such that  $x = A_1 \times A_2$ , then,

$$e_x = \sqrt{A_2^2 e_1^2 + A_1^2 e_2^2} \dots \dots \dots (3)$$

in which,  $e_x$  is the error in the quantity,  $x$ ;  $e_2$  and  $e_1$  represent the errors in the quantities,  $A_1$  and  $A_2$ , respectively.

The more general form of this relationship is expressed in terms of the partial derivatives. Thus,

$$d_x = \sqrt{\left[ e_1 \frac{\partial x}{\partial A_1} \right]^2 + \left[ e_2 \frac{\partial x}{\partial A_2} \right]^2 + \dots + \left[ e_n \frac{\partial x}{\partial A_n} \right]^2} \dots \dots \dots (4)$$

*Example 3.*—The area of a rectangular city lot has been determined by the measurements: The length,  $A_1 = 122.3 \pm 0.04$  ft., and the width,  $A_2 = 48.3 \pm 0.03$  ft. What is the probable error in the area?

By Equation (3), since  $x = A_1 A_2$ ,

$$\begin{aligned} e_x &= \sqrt{48.3^2 \times 0.04^2 + 122.3^2 \times 0.03^2} \\ &= \pm 4.1 \text{ sq. ft.} \end{aligned}$$

*Example 4.*—The height of a transit station has been computed from the measurement of a slope distance,  $L = 837.3 \pm 0.2$  ft., and of a vertical angle,  $\alpha = 3^\circ 20' \pm 30''$ . What is the probable error in the calculated elevation of Station A?

$$H = L \sin \alpha$$

and, therefore, by Equation (4),

$$\begin{aligned} e_H &= \sqrt{e_L^2 \sin^2 \alpha + e_\alpha^2 \cos^2 \alpha L^2} \\ &= \sqrt{0.2^2 \times 0.058^2 + 837^2 \times 0.00015^2 \times 0.998^2} \\ E_H &= \pm 0.12 \text{ ft.} \end{aligned}$$

#### SOURCES OF ERROR IN CHAINING

The principal sources of error in chaining may be described briefly as follows:

(a) *Length of Tape,  $E_1$ .*—This source of error arises from the fact that a comparison made between a steel tape and a standard length, is not exact. A certificate given by the U. S. Bureau of Standards for a steel tape, is as follows:

#### "BUREAU OF STANDARDS CERTIFICATE

"This certifies that 100-Foot Steel Tape No. 2432 has been compared with the standards of the United States and, for the intervals indicated, has the following corrections at 62° Fahrenheit when supported horizontally throughout its entire length under a Tension of 12 pounds avoirdupois:

Interval	Correction	Probable Error
(0 to 100 ft.)	—0.002 foot	$\pm 0.0003$
Tension: 20 pounds (0 to 100 ft.)	+0.006 foot	"
Tension: 30 pounds (0 to 100 ft.)	+0.015 foot	"

"Note: The foregoing comparisons were made at the 0- and 100-foot lines on the brass sleeves.

" $A$  + Correction means that the tape is too long, i. e., longer than the nominal length of the interval;  $a$ —Correction that it is shorter by the amount indicated.

"The comparisons of this tape with the United States Bench Standard were made at a temperature of 83° Fahrenheit and in reducing to 62° Fahrenheit, the coefficient of expansion of the tape is assumed to be 0.0000062 per degree Fahrenheit."

While in use a 100-ft. steel tape is assumed to be exactly 100 ft. long; but reference to the certificate shows that for this tape its length at 62° Fahr. and under a tension of 12 lb., is 99.998 ft.  $\pm 0.0003$  ft. Hence, the cumulate is 0.002 ft. and the systematic error is  $\pm 0.0003$  ft.

(b) *Temperature,  $E_1$ .*—It will be noted that the U. S. Bureau of Standards certificate states the length of the tape at a temperature of 62° Fahr. and gives the value of the coefficient of expansion as 0.0000062 per degree Fahr. Hence, if the tape in the field has another temperature its length will be changed by an appreciable amount.

If the field temperature is not determined, its effect becomes a systematic error. If the value of the field temperature is determined, the change in length becomes a cumulate and may be eliminated by the proper computations.

However, because the temperature cannot be measured exactly, there will result a corresponding small systematic error in the length of the tape. If it is assumed that the temperature remains approximately constant for a given measurement, the errors resulting from temperature changes are systematic in kind.

(c) *Grade,  $E_g$ .*—Since the horizontal distances only are desired in taping, small errors will always be caused by the slope of the ground. This will be true whether the tape is stretched level or stretched on the ground because in the first case there will be a small deviation from a truly horizontal position and in the latter case there will be a small error in determining the inclination of the slope.

If the tape is stretched level, the resultant error will be systematic in kind because whether the tape is inclined upward or downward the resultant error will have the same sign. If the tape is stretched on the ground and if no correction is applied to the measurements, the errors (as in the case when the tape is not held level) will be systematic in kind. If, however, the inclination of the slope is determined, a cumulate is produced, and the corresponding correction can be applied. However, because of the errors in estimating the slope, small resultant errors will remain in the tape measurements, and because some estimated values of slope will be too great and some too small, the resultant errors will be accidental in kind.

Moreover, it will be noticed in Table 1 that a variation of, say, 1 ft., has different values for different slopes. For example, the variation between a 2% and a 3% slope is accompanied by a variation of 0.03 ft. in the error or cumulate; but the variation between a 6% and a 7% slope is accompanied by a variation of 0.07 ft. in the error or cumulate. This condition must be carefully observed in calculating the probable error due to slope of the ground.

(d) *Alignment,  $E_a$ .*—The effects of errors of alignment are exactly similar to those of grade, except that they can be minimized much more easily.

(e) *Sag,  $E_s$ .*—Whenever it is held off the ground a tape sags. For known conditions of pull, weight, and size of tape, cumulates may be computed and the corresponding corrections applied. Because of errors in determining the values of pull, weight, and size, small errors result. Since the variation in pull is the largest factor in causing the resultant error and because the amount of the pull will vary both above and below the estimated value, this resultant error will be accidental in kind.

If no correction for the effect of sag is applied, a systematic error results. Table 1 gives the values of the cumulates or errors for various conditions.

(f) *Marking Tape Lengths,  $E_m$ .*—The position of the end of the tape is usually marked with a stake, a pin, or kiel. Since this position can never be indicated exactly, and the distance thus indicated is as likely to be too great as too small, there result accidental errors the magnitude of which depend on the care used in marking.

(g) *Pull,  $E_p$ .*—A tape is elastic. It therefore has its correct length only under a given standard pull. For any other pull, the tape will be too long or

75	0.05	..	..	10	0.05	..	..	..	..	..	..

too short and resultant accidental errors are caused. This effect of pull should not be confused with its effect on sag as considered under Article (e).

(h) *Wind,  $E_w$ .*—If a tape is stretched unsupported and a strong wind is blowing, the center of the tape will be carried to one side of the line joining the two ends of the tape. This condition causes an effect similar to, but usually much less than, that of sag.

#### SOURCES OF ERROR IN HORIZONTAL ANGLES

The principal sources of error in the measurement of horizontal angles are: (a) Centering the instrument over a point; (b) sighting a point; (c) reading the verniers; and (d) inaccurate adjustment of the instrument. These errors are mainly accidental in kind. A notable exception is the effect of non-perpendicularity between the line of sight and the horizontal axis of the instrument if, in traversing, the backsight is always taken with the telescope inverted, and the foresight is taken with the telescope normal, or *vice versa*. If this procedure is followed, a systematic error results. It can be largely eliminated and rendered an accidental error if at alternate stations the backsight is taken at the first station with the telescope inverted, and at the next station with the telescope normal. In careful work all the errors of non-adjustment are greatly minimized and rendered accidental in kind by double sighting, the telescope being reversed between sights.

#### EFFECTS OF SYSTEMATIC ERRORS IN TRAVERSING

*Distances.*—The effect of a systematic error in the length of the sides of a traverse is apparent in Fig. 1, in which,  $A B C D E A$  represents the true figure of a given traverse. For an assumed error in the length of the tape it is supposed that the true distance,  $AB$ , is measured as  $AB'$ , the error being  $BB'$ . Also, the true distance,  $BC$ , is measured as  $B' C'$  and the total error at  $C$  is represented by the distance,  $CC'$ . The erroneous traverse,  $AB' C' D' E' A$ , is, therefore, similar in form to, and the sides are parallel with, those of the true figure. The total displacement of any point, as  $C$ , is given by the distance,  $CC'$ . This line is coincident in direction with, and proportional in length to, the line,  $CA$ , which may be called the radial line to the point of beginning,  $A$ . Likewise, the errors,  $DD'$  and  $EE'$ , are coincident in direction with, and proportional in length to, the radials,  $DA$  and  $EA$ , respectively. Since the error,  $EE'$ , is thus coincident with and proportional to the line,  $EA$ , evidently the error of closure at  $A$  is zero, which condition is plainly necessary if a systematic error is present throughout the traverse.

*Angles.*—The effects of the errors in the measurement of angles are accidental in kind, or they may be easily so rendered. Hence, the effect of systematic errors in angles will be disregarded.

#### EFFECTS OF ACCIDENTAL ERRORS IN TRAVERSING

*Distances.*—The total linear error resulting from the accidental errors of measurement of any given side of a traverse, is independent of similar errors in the other sides of the traverse. Accordingly, the total combined effect may be considered to be a function of the length of the traverse only; and since

accidental errors are compensative in their effect, the total probable error resulting from the accidental errors of chaining will be given by the product,  $E_L = e\sqrt{n}$ , in which,  $E_L$  is the total probable error;  $e$ , the probable error of a single tape length; and  $n$ , the number of tape lengths in the traverse.

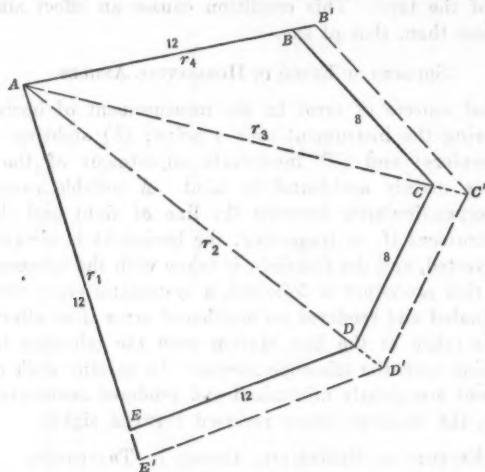

FIG. 1.

**Angles.**—Since the direction of each side of a traverse is determined by measuring the angle between it and the preceding side, it follows that an error made in measuring any given angle, affects all succeeding sides. This condition may be analyzed by reference to Fig. 1. An angular error at  $E$  will cause a linear error at  $A$ , the magnitude of which is given by the relation that,  $e_1 = e_a \times EA$ , in which,  $e_1$  is the linear error at  $A$ ;  $e_a$ , the angular error at  $E$ , expressed in radians; and  $EA$ , the length of the side, which may be expressed as  $r_1$ . Since  $1'$  of arc is very nearly  $0.0003$ , in radians, then, if angles are read so that there is a possible error of  $1'$  in each one,  $e_1 = 0.0003 \times r_1$ .

Likewise, if the angular error at the station,  $D$ , is considered, the angle at  $E$  is now assumed to be without error, and an error in the direction of  $DE$  will displace the point,  $A$ , by an amount equal to the rotation of  $A$  about  $D$  through the angular error,  $e_a$ , at  $D$ . Hence, the linear error at  $A$ , due to angles only, will be given by the relation,  $e_2 = e_a \times 0.0003 r_2$ , and, similarly, for the other stations,  $C$  and  $B$ . According to Equation (2) the total linear error at  $A$  will be,

$$\begin{aligned} E_A &= \sqrt{e_a^2 \times 0.0003^2 (r_1^2 + r_2^2 + \text{etc.})} \\ &= 0.0003 e_a \sqrt{r_1^2 + r_2^2 + \dots + r_n^2} \dots \dots \dots (5) \end{aligned}$$

#### SYSTEMATIC ERRORS IN AN OPEN TRAVERSE

**Distances.**—The total effect of the systematic errors in distances in the case of an open traverse has been indicated in describing the effect of these errors

in a closed traverse. Thus, in Fig. 1, it has been shown that the total error at any point, as  $D$ , for example, is proportional to the radial length,  $DA$ . Accordingly, in Fig. 2, let the points,  $A, B, C, D$ , and  $E$ , represent the transit stations of an open traverse, and let the lengths of the sides, in 100-ft. stations, be shown by the numbers thereon. Thus,  $AB = 600$  ft., etc. Hence, in this traverse, the total systematic error in distance will be proportional to the length,  $EA = 3\,300$  ft.

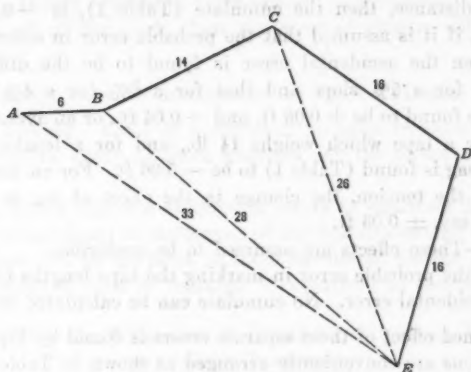

FIG. 2.

*Angles.*—The systematic errors in the measurement of angles will be disregarded in this paper.

#### ACCIDENTAL ERRORS IN AN OPEN TRAVERSE

The total effect of the accidental errors both in distances and in angles will be of a similar nature, and the probable errors are calculated in the same manner, as those for the closed traverse.

#### APPLICATIONS OF THE ANALYSIS TO A CLOSED TRAVERSE

Example 5 illustrates the application of this method of analysis to a closed traverse.

*Example 5.*—In Fig. 1, let the lengths of the sides be:  $AB = 12$ ;  $BC = 8$ ;  $CD = 8$ ;  $DE = 12$ ; and  $EA = 12$  stations, respectively. The traverse was run under the following conditions: The tape was  $100.03 \pm 0.01$  ft. at  $62^\circ$  Fahr. when supported throughout under a tension of 12 lb.; the estimated average temperature of the tape was  $90^\circ$  Fahr.; the weight of the tape was  $1\frac{1}{2}$  lb.; the average ground slope was 5%; the country was partly open and partly wooden so that, for one-half the distance, the tape was held horizontal (unsupported) and, for the other half, it was held on the sloping ground; the average error in marking the tape lengths was  $\pm 0.05$  ft.; and the average error in measuring the angles was  $01'$ . What is the calculated total probable error of closure?

*Errors in Chaining.*—The magnitude of the cumulates and the probable errors may be calculated as follows:

( $E_t$ ).—Assuming the tape to be compared with a standard tape, the length is found to be  $100.03 \pm 0.01$  ft. at  $62^\circ$  Fahr. Hence, the cumulate is  $+0.03$  ft., and the systematic error is  $\pm 0.01$  ft.

( $E_i$ ).—It is assumed that the field temperature is estimated to be  $90^\circ$  Fahr. and that the probable error in this estimation is  $15^\circ$  Fahr. Hence, the cumulate (Table 1) is  $+0.02$  ft. and the systematic error is  $\pm 0.01$  ft.

( $E_g$ ).—If the average slope is 5%, and if the tape is held on the ground one-half the distance, then the cumulate (Table 1), is  $-0.12$  ft. per tape length. Also, if it is assumed that the probable error in estimating the slope is  $\pm 1\%$ , then the accidental error is found to be the difference between the cumulate for a 5% slope and that for a 6% (or a 4%) slope. These differences are found to be  $+0.06$  ft. and  $-0.04$  ft., or an average of  $\pm 0.05$  ft.

( $E_s$ ).—For a tape which weighs  $1\frac{1}{2}$  lb., and for a tension of 12 lb., the cumulate for sag is found (Table 1) to be  $-0.06$  ft. For an assumed variation of  $\pm 3$  lb. in the tension, the change in the effect of sag is  $-0.03$  ft. and  $+0.02$  ft., or, say,  $\pm 0.03$  ft.

( $E_p$ ,  $E_o$ ).—These effects are assumed to be negligible.

( $E_m$ ).—If the probable error in marking the tape lengths is  $\pm 0.1$  ft., this effect is an accidental error. No cumulate can be calculated for this source.

The combined effect of these separate errors is found by Equation (2), and the computations are conveniently arranged as shown in Table 2.

TABLE 2.—COMPUTATIONS TO DETERMINE CHAINING ERRORS  
IN A CLOSED TRAVERSE.

Source.	Cumulate.	Error.	Kind.	Amount, $q$ .	$q^2$ .
$E_t$ .....	$0.03 \times 52 = + 1.6$	$\pm 0.01$	Systematic	0	.....
$E_i$ .....	$0.02 \times 52 = + 1.0$	$\pm 0.01$	Systematic	0	.....
$E_g$ .....	$0.12 \times 26 = - 3.1$	$\pm 0.05$	Accidental	$0.05 \sqrt{26} = \pm 0.3$	0.09
$E_s$ .....	$0.06 \times 26 = - 1.6$	$\pm 0.03$	Accidental	$0.03 \sqrt{26} = \pm 0.15$	0.02
$E_p$ .....	Neglect	.....	.....	.....	.....
$E_o$ .....	Neglect	.....	.....	.....	.....
$E_m$ .....	0	$\pm 0.1$	Accidental	$0.1 \sqrt{52} = \pm 0.7$	0.49
$\Sigma q^2$ .....	.....	.....	.....	.....	0.61

Total correction =  $-6.6$  ft.; total  $E = \sqrt{0.61} = \pm 0.8$  ft.

*Errors in Angles.*—According to Equation (5), the total probable linear error of closure resulting from the accidental errors of measuring the angles is given by the relation:

$$E_A = 1 \times 0.0003 \sqrt{1\,200^2 + 2\,000^2 + 2\,000^2 + 1\,200^2} = \pm 1.0 \text{ ft.}$$

*Total Probable Error of Closure.*—Combining the probable errors for distance and angles, the total probable error resulting from both sources is,

$$E_T = \sqrt{E_L^2 + E_A^2} = \sqrt{1.0^2 + 0.8^2} = \pm 1.3 \text{ ft.}$$

This error of closure (about 1 in 4 000) may seem surprisingly small for the field conditions named. It indicates three important facts: First, that systematic errors in distances and in angles (provided they are present throughout the work) do not affect the error of closure; second, that the total errors of traversing can be easily and largely reduced if the cumulates are removed by simple calculations or by systematic field methods; and, third, that the computations are based on the assumption that the errors are accidental in kind. If any sources of error operate as systematic errors through a part and not all of the work, then the error of closure will be seriously affected thereby.

#### APPLICATION OF ANALYSIS TO AN OPEN TRAVERSE

*Errors in Chaining.*—Let Fig. 2 represent an open traverse for which the same field conditions apply as those assumed for the closed traverse of the previous case.

It has been shown that the systematic errors in chaining from one point to another are proportional to the length of the line connecting these points.

The cumulates will be the same as those calculated for the closed traverse and the total probable error in chaining is calculated as shown in Table 3.

TABLE 3.—COMPUTATIONS TO DETERMINE CHAINING ERRORS  
IN AN OPEN TRAVERSE.

Source.	Kind.	Amount, $q$ .	$q^2$ .
$E_L$ .....	Systematic	$0.01 \times 33 = \pm 0.33$	0.11
$E_L$ .....	Systematic	$0.01 \times 33 = \pm 0.33$	0.11
$E_S$ .....	Accidental	$0.05 \times \sqrt{26} = \pm 0.26$	0.09
$E_S$ .....	Accidental	$0.03 \times \sqrt{26} = \pm 0.15$	0.03
$E_P$ .....	Neglect	.....	....
$E_O$ .....	Neglect	.....	....
$E_m$ .....	Accidental	$0.1 \times \sqrt{52} = \pm 0.7$	0.49
$\Sigma q^2 =$ .....			0.84

Total  $E_L = \pm 0.9$  ft.

*Errors in Angles.*—The final error resulting from accidental errors in measuring the angles is calculated by Equation (2) as follows:

$$E_A = 1 \times 0.0003 \sqrt{2\,800^2 + 2\,600^2 + 1\,600^2} = \pm 1.2 \text{ ft.}$$

*Errors in Chaining and in Angles Combined.*—The combined effect of the errors in chaining and in angles may be represented by  $E_T$  and, therefore,

$$E_T = \sqrt{E_L^2 + E_A^2} = \sqrt{0.9^2 + 1.2^2} = \pm 1.5 \text{ ft.}$$

It may be noted that this traverse has the same length as that of the closed traverse, and the difference in magnitude between the errors of closure of  $\pm 1.3$  ft. for the closed, and  $\pm 1.5$  ft. for the open, traverse is caused entirely by systematic errors, operative in both cases. These were eliminated

in the closed traverse, but could not be eliminated in the open traverse. This condition calls attention to the necessity of giving careful attention to sources of systematic errors for traverses which do not close, if the errors are not to exceed prescribed limits.

#### PREPARING SPECIFICATIONS

*General Procedure.*—In the preceding pages a method has been indicated whereby the total probable error of displacement of the terminal point of a traverse can be calculated if the field conditions are known. A principal purpose of this paper, however, is to indicate the reverse procedure; that is, for a known permissible error of displacement of the terminal point of a traverse, to write specifications for the field work such as will yield the desired results. Assuming that the permissible total error of displacement and the field conditions are known, the successive steps in the procedure are, as follows:

(a) Assign the total permissible error to the two general sources of error, namely, those of angles and distance, respectively.

(b) Assign values to the separate sources of error in the chaining such that their combined effect will not exceed the amount assigned to distance under Step (a).

(c) Calculate the permissible angular error for each transit station such that the combined effect will not exceed the amount assigned to angles under Step (a).

(d) Write the specifications to govern the field work in accordance with the values found under Steps (b) and (c).

*Example 6.*—An open transit-tape traverse approximately 1 mile long is to be run with a total permissible error of displacement of 1.0 ft. The ground is rolling with an average slope of about 6%; it is partly wooded and partly open, so that for one-half the distance the tape is held unsupported and for the other half it is held on the sloping ground; the shape of the traverse is sketched as shown in Fig. 2. It is required to write specifications for the field work involved:

(a) For this traverse an equal amount of permissible error will be assigned to distance and to angles. Accordingly, by Equation (2),

$$1 \text{ ft.} = \sqrt{E_L^2 + E_A^2}$$

or,

$$1 \text{ ft.} = 2 E_L^2$$

hence,

$$E_L = E_A = \pm 0.7 \text{ ft.}$$

(b) By arranging the computations as shown in Table 4, an estimate of the distribution of various chaining errors is obtained.

(c) It is assumed that systematic errors in measuring angles will be eliminated in the field and the permissible error will be calculated for accidental errors only. The values of the radial distances,  $r$ , are estimated; hence,

$$E_A = \pm 0.6 \text{ ft.} = e_a \sqrt{2 \ 800^2 + 2 \ 600^2 + 1 \ 600^2}$$

$$e_a = \pm \frac{0.6}{4 \ 100} = 0.00015 = \pm 30''$$

(d) According to the values assigned to the various sources of error under Steps (b) and (c), the following specifications will apply to the field work:

The length of the tape ( $E_l$ ) shall be known within  $\pm 0.005$  ft.

The temperature of the tape ( $E_t$ ) shall be determined within  $15^\circ$  Fahr.

The slope of the ground ( $E_g$ ) shall be estimated correctly within an average error of 1 per cent.

The tension on the tape ( $E_s$ ) to compensate for sag (weight,  $1\frac{1}{2}$  lb.) shall not vary from the standard tension (12 lb.) by an average error greater than 3 lb.

TABLE 4.—COMPUTATIONS FOR DETERMINING CHAINING ERRORS IN EXAMPLE 6.

Source.	Kind.	Amount, $q$ .	$q^2$ .
$E_l$ .....	Systematic	$0.005 \times 33 = \pm 0.16$	0.03
$E_t$ .....	Systematic	$0.01 \times 33 = \pm 0.33$	0.11
$E_g$ .....	Accidental	$0.06 \times \sqrt{26} = \pm 0.30$	0.09
$E_s$ .....	Accidental	$0.03 \times \sqrt{26} = \pm 0.15$	0.03
$E_p$ .....	Neglect	.....	.....
$E_o$ .....	Neglect	.....	.....
$E_m$ .....	Accidental	$0.05 \times \sqrt{52} = \pm 0.35$	0.12
$\Sigma q^2 =$ .....			0.38

$$E_L = \pm 0.6 \text{ ft.}$$

Errors due to variations in pull ( $E_p$ ) may be neglected.

Errors due to variations from true alignment ( $E_o$ ) may be neglected.

The positions of the ends of the tape shall be marked in such a manner that the average error ( $E_m$ ) shall not exceed  $\pm 0.05$  ft.

The average error ( $E_a$ ) in measuring the angles shall not exceed  $\pm 30''$ .

#### STADIA MEASUREMENTS

*Analysis.*—The measurement of horizontal distances by the stadia method is affected by the systematic errors in the determination of the interval factor,  $K$ , differential refraction, inclination of the rod, etc., and by the accidental errors of reading the rod intercept,  $S$ , the vertical angle,  $\alpha$ , etc. The effects of these errors, both for closed and for open traverses, will be similar in nature to those described for chaining.

The stadia formula for the horizontal distance is,

$$L = K S \cos^2 \alpha + (F + c) \cos \alpha \dots \dots \dots (6)$$

in which,  $L$  is the distance;  $S$ , the rod intercept;  $K$ , the factor interval;  $\alpha$ , the vertical angle;  $F$ , the principal focal length of the objective lens; and  $c$ , the distance from the objective lens to the vertical axis of the instrument. The value,  $(F + c) \cos \alpha$ , is negligible and will be disregarded.

According to Equation (4),

$$E_L = \sqrt{(e_k S \cos^2 \alpha \times N)^2 + (\sqrt{N} K e_s \cos^2 \alpha)^2 + (\sqrt{N} K S e_a \sin 2 \alpha)^2}$$

in which,  $E_L$  is the total probable error, and  $N$  is the number of stadia readings.

*Specifications.*—The specifications for any transit-stadia traverse may be prepared by the following procedure (see Steps (a) to (d), page 690): (1) Decide on the total permissible error; (2) assume average values for  $S$  and  $\alpha$  and the probable errors for  $K$ ,  $S$ , and  $\alpha$ ; namely,  $e_k$ ,  $e_s$ , and  $e_\alpha$ ; (3) compute the total probable error; (4) revise the assumed values of the probable errors, if necessary, to meet the required degree of accuracy; and (5) write specifications for field work.

*Example 7.*—It is desired to measure the length of the traverse shown in Fig. 2 by the stadia method such that the probable error of displacement of the point,  $E$ , shall not exceed  $\pm 10$  ft. Write specifications for the field work:

(1) The permissible probable error is  $\pm 10$  ft.

(2) The average values are assumed to be  $S = 5.00$  ft.;  $\alpha = 3^\circ$ ;  $e_k = \pm 0.3$ ;  $e_s = \pm 0.03$  ft.; and  $e_\alpha = \pm 02'$ .

(3) In this example the error,  $e_k$ , is a systematic error, and  $e_s$  and  $e_\alpha$  are accidental errors. Since the first term under the radical represents the systematic error,  $n$ , for this term, will be  $\frac{33}{5} = 7$ , and for the second and third terms,  $n$  will be  $\frac{52}{5} = 10$ . Hence,

$$E_L = \sqrt{(0.3 \times 5.00 \times 0.999^2 \times 7)^2 + (\sqrt{10} \times 100 \times 0.03 \times 0.999^2)^2 + (\sqrt{10} \times 100 \times 5.00 \times 0.0006 \times 0.11)^2}$$

$$= \pm \sqrt{10^2 + 9^2 + 0.1^2} = \pm 14 \text{ ft.}$$

(4) The calculated value,  $\pm 14$  ft., is greater than the permissible amount of  $\pm 10$  ft. It is noticed that the largest share of the total error is caused by the error,  $e_k$ ; hence, it is assumed that by a more careful determination this is reduced to  $\pm 0.1$  ft.; it is also noticed that  $e_s$  yields only a very small error, and it will expedite the field work to increase this permissible error to  $\pm 5'$ . Using the revised values,

$$E_L = \pm \sqrt{3.3^2 + 9^2 + 0.3^2} = \pm 9.5 \text{ ft.}$$

(5) The specifications for the field work are:

- (a) The stadia factor interval shall be determined within a maximum error of  $\pm 0.1$ .
- (b) The average error in reading the rod intercept shall not exceed  $\pm 0.03$  ft.
- (c) The average error in reading the vertical angles shall not exceed  $\pm 05'$ .

*Remarks.*—The results determined in Example 7 show that the accuracy of stadia measurements is increased by reducing the systematic errors, and that, for small vertical angles, the effect of the error,  $e_s$ , is quite negligible. For large angles, however, the analysis gives a method for determining the required degree of precision in all factors.

## STADIA LEVELING

The procedure for preparing specifications for the work of stadia leveling is the same as for stadia traversing.

*Example 8.*—It is desired to run a line of stadia levels 5 miles long with a permissible error of closure of  $\pm 3.0$  ft. Write specifications for the field work:

(a) The permissible error of closure is  $\pm 3.0$  ft.

(b) Since by the methods used in stadia leveling all errors become accidental in kind and, therefore, compensative, the average permissible error for a single reading may be calculated. Thus,

$$e_s = \frac{E_t}{\sqrt{n}} \dots \dots \dots (7)$$

in which,  $e_s$  is the probable error of a single reading;  $E_t$ , the total probable error; and  $n$ , the number of observations. For a traverse 5 miles long and for average sights of 400 ft., the number of sights will be about 65. Hence,

$$e_s = \frac{3.0}{\sqrt{65}} = \pm 0.37 \text{ ft.}$$

(c) Assume the stadia constant,  $K$ , to be known with a probable error of  $\pm 0.3$  ft.; the rod intercept to be read with a probable error of  $\pm 0.03$  ft.; and the vertical angle to be measured with a probable error of  $\pm 02'$ . Accordingly,  $e_k = \pm 0.3$  ft.;  $e_s = \pm 0.03$  ft.; and  $e_a = \pm 02'$ .

The stadia formula for the difference in elevation,  $V$ , is given by the relation,

$$V = \frac{1}{2} K S \sin 2 \alpha + (F + c) \sin \alpha$$

The quantity,  $(F + c) \sin \alpha$ , will be neglected in the following calculations.

(d) By Equation (4) and by assuming the average rod intercept to be 4.00 ft., and the average vertical angle,  $\alpha$ , to be  $3^\circ$ :

$$\begin{aligned} e_s &= \sqrt{\left(\frac{1}{2} e_k \times s \times \sin 2 \alpha\right)^2 + \left(\frac{1}{2} K e_s \sin 2 \alpha\right)^2 + \left(\frac{1}{2} K s e_a 2 \cos \alpha\right)^2} \\ &= \sqrt{\left(\frac{1}{2} \times 0.3 \times 4.00 \times 0.11\right)^2 + \left(\frac{1}{2} \times 100 \times 0.03 \times 0.11\right)^2} \\ &\quad + \left(\frac{1}{2} \times 100 \times 4.00 \times 2 \times 0.0006 \times 0.99\right)^2 \\ &= \sqrt{0.07^2 + 0.17^2 + 0.24^2} = \pm 0.30 \end{aligned}$$

It is seen that the assumptions in Step (d) yield a probable error,  $e_s = \pm 0.30$  ft., which is less than that required under Step (b). Accordingly, the probable error in reading the rod may be increased to  $\pm 0.04$  ft. Using this value, the total probable error,  $e_s$ , equals  $\pm 0.33$  ft., which is satisfactory.

(e) The specifications for the field work are:

- 1.—The stadia constant,  $K$ , shall be determined with a probable error not exceeding  $\pm 0.3$ .
- 2.—The probable error in reading the rod shall not exceed  $\pm 0.04$  ft.
- 3.—The probable error in reading the vertical angles shall not exceed  $\pm 02'$ .

#### CONCLUSION

The actual behavior of errors agrees more nearly with their theoretical characteristics the more carefully the measurements are made. In other words, if the conditions under which the measurements are made, are carefully controlled, the systematic and accidental errors can be more perfectly classified than if the control of the measurements is less complete. Accordingly, theoretical and actual results, as regards the errors in surveying measurements, will agree more closely under the former than under the latter conditions. However, for the relatively crude measurements of low precision it is believed that the speed of the work can be increased and the character of the results greatly improved by the judicious use of the methods here presented.

## DISCUSSION

C. V. HODGSON,\* M. Am. Soc. C. E. (by letter).—The author has outlined a logical method of determining the specifications for accuracy in a survey and goes further by presenting the mechanics of designing them. The method shown is not only logical, but it accords well with engineering principles. In designing a bridge the engineer must know the purpose to be served, the load to be provided for, and then must decide what type of construction will best meet those requirements. The detailed designing can then be begun and the strength of the individual members computed. Similarly, in a survey, the purpose must first be clearly understood, the requirements of accuracy and specialized data to be met must be formulated, and then decision as to the type of survey and kind of instruments to be used, can be made. The specifications for the strength, or accuracy, of the individual operations must then be determined.

Although the method of writing specifications for a survey described by the author is not new in principle, it shows in a clear manner the method of combining the errors attributable to each of a number of associated factors in a surveying operation and emphasizes the important distinction between a systematic and an accidental error. This distinction is the most essential factor to be borne in mind by the surveyor, except for the necessity of adopting methods which will avoid the possibility of mistakes or blunders remaining undetected. One wishes that the sentence in Professor Rayner's definition of "Mistakes" were always true—that "they are detected by checking the work and are eliminated by applying corrections." Despite elaborate systems of checking, the chances for mistakes have been found by all surveyors to be surprisingly numerous, and there is usually the possibility that some blunder will not be detected by the field checks or by the office computation.

The examples given in the paper show strikingly the difference in the rates at which systematic errors and accidental errors accumulate. A systematic error of  $\pm 0.1$  ft. per tape length with a 100-ft. tape, will give an error of 1 part in 1 000, and this error is independent of the number of tape lengths. An accidental error of  $\pm 0.1$  ft. per tape length, in 100 tape lengths, will represent a probable error of  $\pm 1.0$  ft., or 1 part in 10 000. The principal aim of the surveyor in securing a specified accuracy is to reduce systematic errors to a permissible limit by his methods of measurement, and to make certain that what he regards as accidental errors do not tend to become systematic ones. For instance, in Table 4, the estimated tension is taken to vary from the standard tension by a probable error not greater than 3 lb. and this is considered to be an accidental error. However, if the estimation of tension should be consistently higher or lower than the standard tension, as would conceivably be the case in actual practice, a systematic error would be introduced which would accumulate at a different rate than an accidental error. The same principle would apply to the estimation of temperatures or slope of ground.

\* Asst. Chf., Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C. Major Hodgson died May 19, 1929.

It is probable that some may question the adequacy of the definition given for "Error", which states that "an error always is a quantity of which both the magnitude and the sign are unknown." That part of the definition relating to the sign does not seem to be correct or essential, because the error due to the wind effect of a suspended tape is always such as to make the measured length too large, as is also the error due to lack of alignment of a tape. Other examples of the same tenor could be cited. Also, many will prefer a definition for "Systematic Error" which will provide that it need not be always of the same (unknown) sign, but instead that it shall follow some definite law or relation. For instance, the temperature error in a series of tape measurements may conceivably cause both minus and plus errors at different parts of the same series of measurements, because the temperature varies above and below that at which the tape is standard, but since the error varies in accordance with some definite law, it may be called systematic.

C. KELSEY MATHEWS,\* Assoc. M. Am. Soc. C. E. (by letter).—The author has presented this topic in a manner that should appeal to the engineering mind, inasmuch as the subject of specification writing for the assurance of proper results by an economic process constitutes a major part of the design of all engineering projects. Engineers have been more or less altruistic in attempting to obtain the ultimate economy for the client through refinements in design and construction and have neglected to apply the same principles of economy in their own work. The principles set forth in the paper may be applied in a practical way to reduce expenses.

A large part of the expense of an engineering business may be for field surveys. Generally, the conception of the project originates with some one man in the organization, and through him is determined what field information is to be obtained. The manner in which this is to be achieved is generally left to an assistant whose only qualification for directing surveys may be several years' experience in manipulating surveying instruments.

The lack of knowledge of the purpose of the various parts of the survey, the various degrees of precision required, and the methods necessary to secure this precision, generally results in financial loss to the business. The principal in charge of a project should have a thorough knowledge of these factors, and detailed "specifications", either written or oral, depending on the scope of the project, should be given the assistant in charge of surveys, so that the required precision may be obtained at the least cost. In this manner only the manipulation of instruments is left to the field men.

The errors in such manipulation are those of observation and judgment; they are "accidental" in character, and the effect on the result is comparatively small if the surveyors are skilled and experienced. The important factors will be disposed of as "systematic errors and cumulates" by the observance of the requirements of the "specifications". Provision should be made in the specifications for proper methods of checking against mistakes.

There are two obstacles to be overcome in profiting by specification writing for surveys. The first and most important is the ignorance of the "principal"

\* Care Burns & McDonnell Eng. Co., Kansas City, Mo.

as to the existence of the various sources of error. The second is the reticence of self-styled surveyors to observe new ideas which are not consistent with habits acquired through years of manipulating instruments.

The author's analysis and definitions should provide a liberal education, tending to overcome the first obstacle, if the "principal" can be convinced of the economy which will result. The detailed analysis set forth will actually be a post-graduate course to many engineers after learning that a transit may have a "stadia factor interval" different from 100, and that such difference is of much more importance than exceeding care in reading the intercept. In one out of twenty transits of various makes and ages, the writer found that ten had a factor of 100; seven, of 99 or 101; two, of 102; and one, of 105.

The writer knows of engineers who have insisted that plans and specifications shall obtain consistent economy for the client; who, nevertheless, have taken no cognizance of the possibly large cumulative error involved in the stadia interval. At the same time, they read horizontal angles in the same traverse with a magnifying glass on a 1-min. transit.

One topographical survey for a large hydro-electric project, which kept four parties in the field for six months, was made with no other important instructions than to "get two miles of traverse per day". Several days were lost in one instance in computing and re-surveying one traverse, run with two transits, which failed to close "satisfactorily", only to find later that one of the transits was "out of adjustment"; that is, the interval factor was not 100 as assumed. Numerous examples of such uneconomical procedure may be cited, all of which might be eliminated by "specifications".

The application of the laws of accidental errors to surveying measurements and to the propagation of errors through a combination of different measurements and calculations is certainly more reasonable and consistent than its application to some other engineering data, such as flood flows. This is especially true considering the limited records available for most engineering calculations.

The probability curve is determined theoretically only by an infinite number of observations. In determining the probable frequency of a certain maximum flood, based on a limited number of observations which are under no definite control, the truth is only confused by a mass of probability figures. In shooting at a mark, or in estimating the slopes of the various courses of a traverse, the observations are under control, and the deviations from true value will be truly accidental in character. The laws of probability, therefore, will apply with greater mathematical certainty even if the observations are few in number.

The value of specification writing for transit traversing, stadia leveling, or any other form of surveying, can be realized only if the field men understand and comply with the specifications. The wording and the minuteness of detail necessary will depend on the type of men for whom they are written.

The writer believes that the "specifications" as outlined by the author in the examples given should be classed as calculations and notes made by and for the principal in charge as a guide for writing the actual specifications. These calculations and notes might be given the assistant in charge of field

work so that the spirit and purpose of the actual specifications might be more easily understood. The knowledge that partial derivatives and a few square roots had been introduced might be confusing to some "practical" surveyors and might not secure the co-operation desired.

Consider, for instance, the data given in Example 6. The eight specifications listed under Section (d) are the principal's notes. The suggested working specifications to be handed to the field assistant would read as follows:

- (1) Compare the tape with standard by stretching between hubs (set permanently near office) at a pull of 12 lb. determined by a small spring balance. Note correction in length to nearest 0.01 ft. and note air temperature from the thermometer to nearest degree, before leaving office.
- (2) In the field, estimate temperature of tape at beginning and completion of chaining and note to nearest 10 degrees.
- (3) Estimate average slope by aid of hand level for each critical change in the slope and note to nearest 1 per cent.
- (4) and (5) Hold chain parallel to the general slope of the course, or on the ground, maintaining as nearly as possible, by estimation, a 12-lb. pull.
- (6) Set flag on forward station and have rear chainman align head chainman therewith when deviation is apparently more than 1 ft.
- (7) Stick pins or mark, without elaborate care, so that the station is marked within 0.05 ft. of apparent exact position.
- (8) Use 1-min. transit; measure all angles to right with telescope direct; read and record angle to nearest minute without magnifying glass; reverse telescope, reset plates, and read and record angle to right again; read needle and record to nearest degree.

*Checks.*—The field work may be checked as follows: (1) In taping, both chainmen shall calculate all stations from pin count and call and check; (2) both chainmen shall call and check all pluses; (3) in measuring angles, duplicate all readings; and (4) read the compass.

Specifications for calculating and removing cumulates should be written, or, preferably a blank form should be provided for entering the corrections with the proper sign, and the corrected chaining.

The sixth specification under Section (d) stipulates that, "errors due to variations from true alignment ( $E_0$ ) may be neglected". The writer has included an item (corresponding to Example 6) that controls the precision desirable for this source. The author has stated in Item (d), under "Sources of Error in Chaining", that, "the effects of errors of alignment are exactly similar to those of grade, except that they can be minimized much more easily." The writer recognizes the error due to alignment in the sense of chaining along a curved line between two traverse hubs rather than along a straight line, and acknowledges that this error may be neglected if a sincere attempt is made to chain toward the forward hub. The source of error which should be controlled is the "zigzag" deviation of the ends of the tape from the general line of chaining independent of its general curvature. The first error is similar to that introduced by chaining parallel to, or on, the general ground slope without correcting to horizontal. This error would amount

approximately to 0.1 ft. in Example 6 if the average offset from a straight line between hubs were 3 ft. The second error is similar to that introduced by the ends of the tape not being at the same elevation in attempting to measure horizontal distance directly, or by not being in a plane parallel to the general slope in chaining according to the problem assumptions. This error would amount approximately to 0.25 ft. in Example 6 if the average "zigzag" deviation of the end of tape from the general line of chaining were 1 ft.

An interesting point is developed in connection with this subject when a comparison of the precision obtainable by chaining on the ground and removing the slope cumulate is made with that obtainable by attempting to hold the tape horizontally and set the point by plumb-bob.

If the grade is estimated for every material change in the general slope along a traverse with an average error of 1% (which may be done quickly with the aid of a hand level), the error in the corrected length of traverse will be "accidental" and will amount to the square root of the number of estimates times the average error in length per estimate. In Example 6, if there are 25 estimations of slope (1 per station), the probable error due to estimating grade would be  $0.06 \text{ ft.} \times \sqrt{0.25} = \pm 0.30 \text{ ft.}$

The author has assumed that, for the remaining half of the traverse, the tape is held unsupported and horizontally, but has allowed nothing for the error introduced because of the ends of the tape not being in the same horizontal plane. This error would be  $33 \times 0.005 \text{ ft.} = 0.17 \text{ ft.}$ , if the deviation from horizontal were 1 per cent. If the average slope were 3%, or less, the precision obtainable by the two methods would be nearly the same, with the time advantage in favor of chaining on the ground or parallel to the general slope.

The determination of the stadia constant within a probable error of  $\pm 0.1$  is rather unusual, and the method of obtaining it should be outlined in detail for field specifications. These might read as follows, for Example 7:

"Ten arbitrary points on level ground and in line from the transit shall be marked up to approximately 1000 ft. The intercept shall be read to the nearest 0.01 ft. on each distance. The distance to each shall then be taped and recorded to the nearest foot. The value of  $K$  for each distance shall then be calculated from the formula,  $K = \left( \frac{D - 1}{S} \right)$ , and recorded to the nearest 0.1. The mean of the ten values shall be calculated to the nearest four significant figures and used for  $K$ ."

These suggested specifications for determining  $K$  are calculated from an assumed probable error of  $\pm 0.003 \text{ ft.}$  in reading the intercept and of  $\pm 0.3 \text{ ft.}$  in distance, which is equivalent to a probable error of  $\pm 0.3 \text{ ft.}$  in  $K$ . The probable error in the mean of ten determinations would then be approximately  $\pm 0.1 \text{ ft.}$  The probable error in  $K$  could be checked more accurately by computing the residuals for each determination afterward.

It is necessary to have the proper perspective with regard to the surveys for a project, in the same sense as a proper perspective is necessary in the conception of the project as a whole. In other words, an economical survey cannot be made by an unrelated system of measurements any more than a

structure can be built economically by adding arbitrary units to a nucleus. The designer must visualize the component parts assembled, and must know their correlation.

The author is to be congratulated on presenting a paper containing the fundamental principles necessary to attain the proper perspective with regard to the surveys, and also practical suggestions for their direction and execution.

HOWARD S. RAPPLEYE,\* ASSOC. M. AM. SOC. C. E. (by letter).—This paper deals with a phase of surveying that has received little attention in the past. With the possible exception of organizations charged with the execution of extensive surveys over large areas, engineers have fallen into the habit of using more or less rule-of-thumb methods of deciding what instrumental equipment and field procedure is to be used for a given survey. It is undoubtedly true that a vast amount of time and effort can be saved by properly drawn specifications regarding the necessary accuracy of the various steps in the making of a survey. It stands to reason that such specifications should be based on thorough studies of the effect of the various sources of error, considered singly and in combination, on the accuracy of the final results.

The writer believes, however, that specifications should be drawn for the several classes of surveys rather than for individual surveys. Except, perhaps, in the case of property surveys, it is not usually known beforehand what the shape of the traverse will be, nor is it usual to have any very detailed knowledge of conditions to be encountered along the route of a given traverse. This is especially true in certain parts of the country where, within the small space occupied by a farm of 100 acres, the character of the land may vary from almost perfectly flat bottom-land to the most rugged side-hill topography.

The concept that an error must be an unknown quantity in both sign and magnitude is open to discussion. The error due to phase in pointing on a signal is certainly systematic, but its sign is not necessarily unknown. The definition of a "Systematic Error" is likewise open to question, although it is true that it derives its name and character from the fact that its algebraic sign remains the same. The fact that this sign is always in doubt seems to be subject to debate. Take, for example, a cross-wind blowing against an unsupported tape. This certainly introduces a systematic error in the measurements, but the sign of the error is positively known since it always shortens the distance between the terminal marks of the tape and, thereby, causes measurements under these conditions to be too long.

That the effect of a systematic error cannot be eliminated by systematic field methods appears to be also a debatable subject. Suppose that a line is taped along a smooth concrete roadway, and a finely pointed pencil is used to mark the tape ends. It is conceivable that a tapeman might have a persistent tendency to mark to the right of the graduation at the end of the tape by a small amount. This tendency certainly would produce a systematic error.

\* Assoc. Mathematician, Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

Now, suppose the measurement to be progressing toward the forward contact man's right, as he kneels by the tape. If he has a tendency to mark to the right he will be marking ahead, and his resulting measure will be too short. Suppose, then, that the measure is repeated in the backward direction, but that the observer stays on the same side of the tape. His tendency to mark to the right will then cause him to mark behind and his measure on the backward running will be too long. The mean of the two measures should then be free from his personal equation or systematic error in marking.

The first part of the definition of a "Cumulate" represents what the writer is in the habit of referring to as a correction. Any systematic error in surveying that can be eliminated by calculation takes on the character of a correction and does not affect the agreement of the final results. Any source of systematic error which can be, and is, eliminated by systematic field methods never appears in the final discrepancies at all. It would seem to be wise to retain the term, "correction", as referring to a systematic error for which an allowance is made by computation, and, since the other feature of the definition of a "cumulate" fails to enter the final results when proper field methods are used, it would seem that the necessity for the new term is slight at best.

"Mistakes" are the result, not only of confusion in the mind of the observer, but also of confusion in the mind of the recorder or from misunderstandings arising between them. If mistakes are of a size considerably larger than the errors of observation, they are detected because of their lack of conformity when measures are repeated but, in the case of small mistakes of a size equal to or only slightly larger than the errors of observation, they may be easily mixed up with legitimate errors and be treated accordingly.

Regarding temperature errors in tape measurements: If the temperature is assumed to remain constant, as suggested, the error is systematic to be sure, but if the assumed temperature is between the maximum and minimum actually encountered during the course of the work, the sign of the error will change, depending on whether this temperature is above or below the actual temperature at the time, and the resulting errors will not be strictly systematic throughout the whole traverse. It is noted that, in Table 1, Professor Rayner has computed values of  $E_t$  to the nearest 0.005 ft. per 100 ft. The writer suggests that this should be the nearest 0.001 ft., in order to be consistent with values of  $E_s$  in the same table.

To use the telescope reversed on the backsight and direct on the foresight at the odd numbered set-ups, and direct on the backsight and reversed on the foresight at the even numbered set-ups, will merely serve to place the error of adjustment of the line of collimation alternately plus and minus as the instrument progresses around the traverse. It seems to the writer that it would be better to let the error accumulate in a closed traverse and then eliminate it by distribution after the traverse is closed. Theoretically, this would give the correct angle at each station where the suggested procedure would make each angle in error by the same amount, but with the sign changing at each set-up along the traverse. In work in which considerable accuracy in angles is required, a reversal at each station is desirable; reading

double deflections or using the transit as a direction instrument will accomplish the desired end.

In the comparison of the computed probable errors, under the heading "Errors in Chaining and in Angles Combined", the author states that the systematic errors were eliminated from the closed traverse, but could not be eliminated from the open traverse. This carries the idea, by inference at least, that systematic errors in an open traverse are more dangerous than in a closed one. It is true that the systematic errors which operate throughout the entire closed traverse do not appear in the final closure, but they are present, nevertheless. If a systematic error of 1 part in 1 000 is present in a closed traverse the accuracy of the survey is only 1 part in 1 000, even if luck is with the surveyor and he happens to get a perfect closure on his return to the initial station.

Under Example 6, Sub-division (a), the permissible error (1 ft.) is substituted as the probable error in a formula. To the writer this seems to be the misuse of a perfectly good formula. The total permissible error should not be assumed to be equal to the probable error.

W. H. RAYNER,\* Assoc. M. Am. Soc. C. E. (by letter).—In the discussion of this paper, exception is taken to the assumption that an error is a quantity of which both the magnitude and the sign are unknown; and also to the corresponding definitions of "Systematic Error" and "Cumulate".

It has seemed to the writer that there always has been an element of confusion in the discussion of the subject of errors because the term, "error", has included both the significant and the non-significant quantities which constitute the difference between any measured value and the corresponding true value. In the paper the significant and non-significant quantities were defined as "error" and "cumulate", respectively.

The analogy is not complete, but there is a similarity between the terms, "cumulate", as used in this discussion, and "tare", as used in weights. To weigh certain commodities a "gross" and a "tare" weight are taken, from which the "net" weight is obtained. The tare is sometimes found by weighing a container and sometimes it is compensated for, by a counterpoise. Thus, the tare weight may be found by a computation (that is, a correction), or it may be eliminated by a systematic procedure. The term, "error", as it has been commonly used, may be said to correspond to a "gross" measurement, including both the significant ("net" corresponding to "error") and the non-significant ("tare", corresponding to "cumulate") quantities.

If the proposed meaning of the term, "error", is accepted, namely, that it is that part of the difference between a true and a measured quantity which remains after the cumulate has been removed, then it is believed that the definition of the term "systematic error" as stated, is correct.

In the discussion it has been stated that,

"That part of the definition relating to the sign does not seem to be correct or essential, because the error due to the wind effect of a suspended tape is always such as to make the measured length too large, as is also the error due to lack of alignment of a tape. Other examples of the same tenor could be cited."

\* Asst. Prof. of Surveying, Univ. of Illinois, Urbana, Ill.

Mr. Rappleye also uses the same example and the additional one that "the error due to phase in pointing on a signal is certainly systematic, but its sign is not necessarily unknown."

In both these statements the sign of the "gross" error is known; but if so, would it not be logical to make an estimated or calculated correction? Thus, the effect of the wind on the tape may be estimated and the correction subtracted from the measured length. After this estimated correction has been applied (that is, after the cumulate has been removed) one cannot then say whether the remaining error is plus or minus, because the estimated correction may have been too large or too small. Similarly, after a correction for phase in sighting a signal has been applied, one cannot say what the sign of the remaining error will be. In passing, it may be stated that the distinction between the terms, "cumulate" and "correction", is that they have opposite signs. The cumulate is the quantity that is removed by applying the corresponding correction. However, probably little harm is done in using the terms interchangeably.

Mr. Rappleye further questions that part of the writer's definition of a systematic error which states that "its effect cannot be removed by systematic field methods". He uses the example of a forward chainman who has a tendency to mark to the right of the end of the tape, the effect of which is eliminated by the process used in measuring forward and back.

Here, again, he is using the term, "error", in its customary meaning and not according to that proposed. To the extent that the effect of measuring to the right is eliminated by a systematic field procedure it is non-significant and has been rendered a cumulate. In this instance the "tare" quantity has been obtained, not by a calculation but by a "counterpoise", that is, a systematic procedure. Surely it must be admitted that a final error remains, due to the effect under consideration. This remaining error, however small, is the significant or true error, and one cannot say what its sign or magnitude is.

The writer agrees that a "systematic error" need not always have the same sign. Of course, such conditions as temperature, direction of the wind and of the sun's rays, change from time to time; but any one of these conditions causes a systematic error only under the condition that its effect has the same sign for a considerable number of consecutive observations. Accordingly, the definition is improved by omitting the word "always", making it read "an error which has the same (unknown) sign, etc."

It may be added that the discussion of the definitions of the terms used is, after all, of little importance as compared with the major proposal with which the paper deals.

Paper No. 1742

### COMMENTS ON THE DESIGN OF SLUDGE DIGESTION TANKS\*

By RICHARD H. GOULD,† M. Am. Soc. C. E.

WITH DISCUSSION BY MESSRS. HARRISON P. EDDY, JOHN R. DOWNES, WILLEM RUDOLFS, EDMUND B. BESSELIEVRE, JERRY DONOHUE, KENNETH ALLEN, AND RICHARD H. GOULD.

#### SYNOPSIS

The digestion of sewage solids is brought about by certain fundamental processes that are common in Nature. These were utilized by Man for the treatment of sewage before the development of the science of bacteriology and before any proper appreciation was had of their nature. Metcalf‡ has given an excellent outline of the use of digestion in the cesspools of London and Paris early in the Nineteenth Century, of the application of the principles involved to small household appliances, and, in the latter part of the century, to the septic tank.

The septic tank has been largely superseded by the Imhoff tank, and in the past few years there has been a decided movement toward the digestion of sewage solids in separate tanks. These developments have been brought about in large measure by efforts to minimize the nuisances attendant on the treatment of sewage; to make the tank effluent more amenable to further treatment; and to reduce the costs of construction and operation.

The purpose of this paper is to indicate the manner in which the experiences of past years in the use of tank treatment and the recently developed scientific knowledge of the bio-chemical actions, are being applied to the design of sludge digestion tanks.

\* Presented at the meeting of the Sanitary Engineering Division, Asheville, N. C., April 21, 1927.

‡ "The Antecedents of the Septic Tank", Leonard Metcalf, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XLVI (1901), p. 456.

## EXPERIENCES WITH SEPTIC TANKS

The long use of septic tanks and cesspools has shown that the anaerobic digestion of sewage solids will reduce these solids very largely in bulk and will leave a residue of an inert, odorless character. This resulting sludge can be handled with relative ease and dried readily. Thus, the septic tank marks a distinct advance over the plain sedimentation tank and brings about a reduction in operating costs through easier sludge handling. Because of the difficulty of properly disposing of the sludge from plain sedimentation tanks the development of odors following septic treatment was probably not increased.

Certain evils, however, attended the use of the septic tank. The sewage became highly charged with odorous gases of decomposition, which were often liberated to the air during subsequent treatment. The effluent did not re-act so easily to aerobic treatment as fresh sewage effluents. During warm weather, at times of heavy gas formation in the tanks, the effluent was contaminated with suspended matter, often to an amount in excess of that in the raw sewage. The usual experience was that considerable odor was developed in the tank itself, both from the gases rising out of the liquid and from those produced in the mats of scum on top.

## EXPERIENCES WITH IMHOFF TANKS

The advantages of the digestion of sewage solids, as shown by the septic tank, were utilized to even better advantage in the Imhoff tank. While retaining the anaerobic decomposition of solids, this tank permitted the flowing sewage to retain its freshness by confining it to a special compartment separated from the decomposing sludge and by allowing the freshly deposited solids to pass to the sludge compartment by gravity through slots constructed so as to prevent the contamination of the flowing sewage by gas-lifted solids. Only the oldest and most thoroughly digested sludge is removed from good Imhoff tanks, and is probably somewhat better than that from septic tanks. The control of digestion is such that no odorous gases are liberated from the sludge compartment. A properly designed and operated Imhoff tank is still considered eminently satisfactory for the handling of sewage solids and the preliminary treatment of sewage.

Although there are many successful Imhoff tank installations, others to a considerable number in the aggregate have given disappointment. Perhaps in the majority of cases this failure can be traced to faulty operation, but often the original design has been at fault. Too often units for capacities that have proved satisfactory, have been applied to new designs without proper appreciation of the loadings, form of tanks, and climatic conditions under which the first results were obtained. Eddy,\* in an exhaustive comparison of four Imhoff tanks, two of which gave satisfactory results, summarizes reasons for differences in behavior under twenty-five separate headings. The multiplicity of these considerations, many of which are entirely neglected by some and interpreted in accordance with individual bias by others, seems to explain adequately the reason why there are so many poor designs. Fortunately, later

\* "Imhoff Tanks—Reasons for Differences in Behavior," by Harrison P. Eddy, M. Am. Soc. C. E., *Transactions, Am. Soc. C. E.*, Vol. 88 (1925), p. 465.

researches have tended to minimize some of the uncertainties formerly existing.

Granted adequate design, there are still reasons in some cases for a search for better appliances. The Imhoff tank with its two stories, one above the other, is a deep structure. The usual location for disposal plants is in low ground with a high ground-water level. The result is heavy construction costs for deep tanks. The fact that the sedimentation compartment and the sludge compartment of an Imhoff tank are combined in one unit makes it impossible to change the relation between the two. It is sometimes difficult to estimate in advance the exact flow to be treated and the sludge quantities to be cared for; indeed, these factors may change their relation after a number of years of operation. The tank, however, is fixed and cannot be altered to correspond. The temperature in the sludge compartment is essentially the same as that of the flowing sewage. In northern climates the cold winter sewage retards digestion greatly. Furthermore, it is not practical to heat the digestion compartment artificially, and gain the resulting benefits.

#### EARLY EXAMPLE OF SEPARATE DIGESTION

The digestion of sludge in tanks separated from the flowing sewage has been successfully accomplished in England and in Germany. In America the first notable example on a large scale was at Baltimore, Md. There, following unfortunate results with Imhoff tanks, separate sludge digestion was developed. The early work did not have the advantages of previous large scale experience or of scientific research. Certain unanticipated results were obtained. At times, sludge that was expected to settle came largely to the surface; and there were other difficulties in handling the sludge, in lack of capacity, and in odor production. It was demonstrated, however, that separate digestion was possible and that its costs were reasonable. Under the conditions and arrangements provided, large unit capacities were found to be necessary.

#### RESEARCH ON DIGESTION PROBLEMS

A most promising step toward better design of digestion tanks lies in the scientific research carried on within the past few years. The important work done at the New Jersey State Sewage Experiment Station at Rutgers College, New Brunswick, N. J., by Dr. Willem Rudolfs has been checked, in many respects, by parallel studies at Harvard University by Fair and Baity under the Rockefeller Foundation Fellowship. Other experimenters have been at work elsewhere in the United States, as well as in Germany and in Russia.

In carefully controlled laboratory experiments, it has been possible to separate the many variable factors that affect digestion and ascribe limiting results to each factor. It should be recognized that the course of digestion in the sludge compartment of an Imhoff tank and in a separate digestion tank is essentially the same, so that knowledge of the surrounding conditions can be applied with equal force to either type of structure. The form of the works may be different and this may alter environmental conditions, but the fundamental processes are the same in each case.

### NATURE OF DIGESTION

Laboratory experiments have demonstrated that in the course of digestion the nature of the early products is acid, followed in the later stages by alkaline products. The most advantageous digestion occurs within a narrow range of acidity and this is best expressed in terms of the hydrogen-ion concentration, as pH-values. Should the pH-value become much less than 7.3, acid foaming may occur; and if much more, that of an alkaline nature may result. Odors result from either extreme condition. Thus, by controlling the pH-value within a narrow range the desired type of digestion—either liquefying or gasifying—may be secured.

Measurements of gas production have been made, and these, in conjunction with actual measurements from tanks in service, indicate that methane gas in worth-while quantities can be collected. As would be expected, the temperature has a large effect on the rate of digestion. Oxygen was found to be detrimental to anaerobic digestion, and to aid, perhaps, in odor production.

### PRACTICAL APPLICATION

The essentials for optimum digestion are few in number and easy to apply. The question of reaction control in tanks of adequate design will normally take care of itself. It is only necessary to ensure that sufficient quantities of sludge in the later stages of digestion, when alkaline products are being given off, are in the tank, to counterbalance the acid production of freshly added solids. This is the criterion that should control tank loading. It is not the volume of tank space available, but the actual presence of a definite quantity of sludge that is important. Dr. Rudolfs believes that the addition each day of fresh solids to the extent of 2% of those already in the tank, both on the dry basis, is permissible without adversely affecting the optimum conditions for digestion, when the temperature is about 70° Fahr. The value of the artificial control of the reaction by the use of lime has been demonstrated in restoring tanks to proper operating conditions. This permits loading beyond that indicated.

The laboratory work is based on the quantity of destructible organic matter in the solids to be treated. The danger of using uniform per capita allowances for sludge digestion space has been frequently shown. Such a unit is convenient and has the value of time-honored use, but it should be defined in such a way as to correspond with sludge of the same volume and character as that deposited from sewage of normal strength under the usual settling tank conditions. On this basis laboratory results showed the digestion capacity required for a particular case to be about 0.8 cu. ft. per capita, provided the reaction and temperature conditions were controlled, whereas about 2.5 cu. ft. per capita would be necessary without such control. This is a ratio of about 1 to 3 in favor of controlled digestion.

### COMPARISON OF LABORATORY AND FIELD RESULTS

Engineers acquainted with Imhoff tanks or digestion tanks, in operation under different conditions, will probably agree that the results shown by the

laboratory tests through the control of digestion are not improbable. In comparing such tanks it should be borne in mind that the sludge capacity for the Imhoff tank is computed as that part below the slots, or even 18 in. below, whereas that of a sludge digestion tank includes the entire water volume. The space for floating sludge in an Imhoff tank may add but little to its digesting capacity; but there is also a space for liquid in most digestion tanks which must not be neglected in any computations for required capacities.

An example of a plant operating under unusually favorable conditions with low digestion capacities is the original installation at Dallas, Tex., designed by James H. Fuertes, M. Am. Soc. C. E. These Imhoff tanks, beginning in January, 1917, operated satisfactorily up to a loading beyond that for which they were designed. The digestion space below the slots was less than 0.5 cu. ft. per capita, as determined by a careful population check, modified somewhat by the volume of suspended solids actually being retained in the tanks. At this loading, however, well-digested sludge was obtained. It was inodorous and could be removed from the drying beds after three to four days of good weather. For a comparison with digestion tanks, the total space in the digestion compartments of these tanks (including that for floating sludge) was equivalent to about 0.9 cu. ft. per capita. It should be noted that the average seasonal temperatures were relatively high and that, in addition, a considerable volume of hot water came from artesian supplies. The range of temperature in the tanks is not known. The form of the sludge wells at Dallas is such that very nearly the entire capacity is available for digestion. Each well serves only one sedimentation chamber.

The loading at Dallas was much higher than is common in America, but it will be recalled that the early recommendations by Dr. Imhoff, for digestion capacities for domestic sewage from separate systems, were not greatly in excess of this quantity. These recommendations were based on the operation of similar plants in the Emscher District, in Germany. The writer has seen a number of those plants in successful operation.

A brief comparison of the per capita digestion capacity at Dallas with that at other more northerly locations is shown in Table 1. This confirms the conclusion that by suitable control it is possible to reduce the required digestion capacity to one-third that otherwise necessary.

Additional confirmation of the conclusions indicated in Table 1, is furnished by results secured at the Joint Disposal Works of Plainfield, N. J. In this case separate digestion tanks, constructed to handle sludge formerly treated in Imhoff tanks, are provided with floating covers, gas collection appliances, and means for artificial heating. John R. Downes, Superintendent and Designer, states that the new tanks have produced good sludge, without odors, under conditions of operation with a continuous loading such that there was only about 0.75 cu. ft. of digestion space per capita. The temperature range was from 65° to 70° Fahr. Formerly, unsatisfactory results were obtained with this same sewage in Imhoff tanks with a nominal digestion capacity below the slots of 1.49 cu. ft. per capita.\* It is doubtful in this latter case whether all this space could be used to full advantage.

#### CONSIDERATIONS AFFECTING DESIGN

How far the possibilities of digestion control may be utilized depends to a large extent on the intelligence with which the plant will be operated and the general policy pursued in the construction of the works. From a theoretical standpoint it is distinctly economical to maintain relatively high temperatures and to control the reaction of the contents. The saving in interest on the extra cost of larger tanks would pay many times over for the heating and lime necessary.

It has been demonstrated that methane gas in worth-while quantities can be collected from digestion tanks. The heating value of this gas is probably more than enough to maintain the desired temperatures. In one case where it is proposed to return surplus activated sludge to the digestion tanks it is estimated that sufficient power can be developed for a system of partial activation. More important than these possible economies are satisfactory operating conditions and results. It is good engineering to allow a certain margin in capacity to assure these ends. Unless the plant is to be operated with intelligence it will be difficult to realize all the possible advantages.

In arriving at the digestion capacity to be provided the question of sludge removal must be carefully considered. For operation at the maximum rating, the loading of fresh solids should be uniform. The removal of sludge throughout the year is a distinct advantage in the operation of the tank itself. This is rarely possible under the usual climatic conditions. If sludge cannot be removed at all times additional capacity must be provided in the tank, or elsewhere, to tide over these shortcomings. The improvement in methods of sludge handling and sludge drying is thus of great importance and has a direct bearing on tank design.

After the required digestion capacity is determined, a form of tank must be selected that will give this capacity in effective space. A flat-bottomed tank does not adversely affect digestion, but may contain dead pockets (as in the corners), that will gradually become filled with inert material and thus may not be considered as effective digestion space. The desirability of providing multiple outlets or mechanical means for maintaining the usefulness

of the entire tank capacity can best be determined by a study of the relative costs involved. The admission of fresh solids to a tank should be controlled so as to distribute them fairly evenly throughout the active zone of the tank and to cause their thorough seeding with the older sludge. A concentration of fresh solids in isolated points is to be avoided.

The preponderance of evidence seems to be strongly in favor of providing covers for digestion tanks. One of the major reasons is to suppress odors. In an open tank a certain amount of oxygen comes in contact with the digesting material and this has been shown to retard digestion and tend, if anything, to increase the odors. If the reaction is not correct a dense scum may form which becomes partly dried on exposure to the air and is the source of objectional odors and flies.

A number of different types of covers have been used or proposed. A simple elevated cover somewhat above the surface prevents the spreading of odors to a certain extent. As usually operated, however, this form admits air to the tank when sludge is drawn, with consequent disadvantage to the digestion process, and possible formation of an explosive mixture of gas. This type is not particularly well adapted to the collection and utilization of the gas produced, as it may permit contamination with air, when sludge or liquid is withdrawn.

Suppressed covers, by keeping the scum submerged, prevent its drying and aid in its digestion. This form has the disadvantage that, in case the tank tends to foam, resulting conditions are aggravated, as the gas and foam must pass through a constricted outlet smaller than the gas vents of an Imhoff tank. The admission of fresh sludge causes an equivalent displacement of liquid which may contain an appreciable quantity of suspended matter. It has appeared desirable in some cases to provide a separate compartment to store this overflow.

A third type, perhaps the most flexible, is the floating cover, such as is installed at the Plainfield works. It rises and falls with the admission and withdrawal of sludge, thus excluding oxygen at all times and ensuring that the gas is uncontaminated. The cover can be operated so as to submerge such scum as is formed, or should foaming develop the vertical displacement of the cover provides space for its accommodation. A modified design has been proposed, much in the form of the ordinary gas-holder, providing a cover and also space for storing the gas produced. For practical utilization of the gas, some such device seems desirable to tide over inequalities in the rates of production and use.

Fresh solids admitted to a digestion tank undergo a reduction in volume by liquefaction and gasification. The digested sludge through its changed character is much more compact than fresh sludge and increasingly so the longer it is allowed to stay in the tank. The sludge withdrawn always has a lower water content than that added. This means that, in order to maintain an adequate volume of old sludge in a tank, liquid must be withdrawn from time to time. By careful selection of the point of withdrawal it is possible to obtain liquid with but little suspended matter, which may be returned to the plant influent without causing much trouble. The quantity of this liquid is

a very small part of the total flow; if it is not so disposed of, it may be filtered on a sand bed.

A separate sludge well, in connection with digestion tanks, is often of distinct advantage. Surplus liquid can be drained to it from the tanks. The solids can be settled out or floated to the surface by the use of alum, the clear liquid pumped to the main influent of the plant, and the solids returned to the digestion tanks. Such a well also furnishes a convenient place for the adjustment of the reaction by circulating sludge from the tanks through the sludge well, adding the necessary lime at this point. When sludge drawn from the sedimentation tanks has a high water content, the sludge well may be used for its concentration. This will be particularly advantageous during cold weather, avoiding the necessity of heating excessive volumes of cold water.

The design of digestion tanks cannot be divorced from that of the other disposal works, nor from the degree of attention that the works will receive when built. The rate and character of the loading, the length of the season over which sludge may be drawn, and the temperatures that can be expected are all factors of vital importance. If it is probable that the plant will not receive careful attention, it may be advisable to add appreciably to the capacity. A nice balance must be struck between the benefits to be secured and the costs of construction and operation necessary to bring them about. A solution that is proper in one case, may be quite inadequate elsewhere.

#### TYPICAL DESIGNS FOR DIGESTION TANKS

The designs for digestion tanks shown in Figs. 1 to 6 illustrate the general trends. While a number of interesting developments are shown, no attempt has been made to indicate all types of tanks built or proposed.

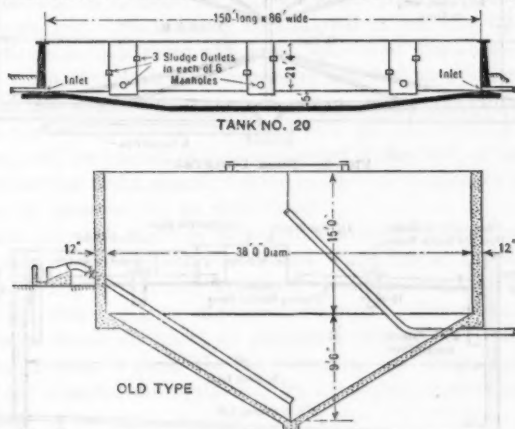

FIG. 1.—BALTIMORE, MD., TANKS.

The tanks at Baltimore, Md. (Fig. 1) are the largest and, at the same time, one of the first examples of separate digestion tanks in America. They use what might be called uncontrolled digestion. So far as is known, no

especial attempt has been made to limit temperatures and reactions, or to suppress surface scums and odors. However, they show conclusively that if sufficient capacity is provided, well-digested sludge can be secured. While some odor is unquestionably present, it is not serious when the size of the plant is considered.

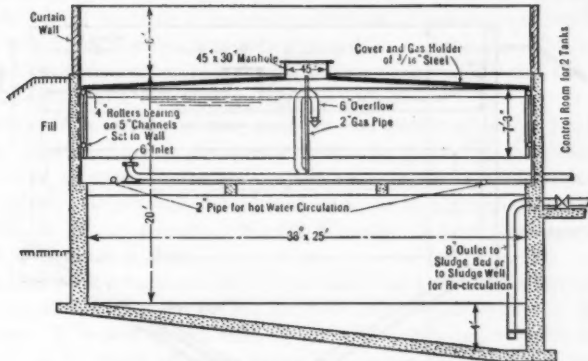

FIG. 5.—LYNBROOK, N. Y., TANK.

The general features of the digestion tanks at Boonton, N. J., are shown in Fig. 2. This plant,\* completed in 1924 by the municipal authorities of Jersey City, N. J., from designs by Clyde Potts, M. Am. Soc. C. E., for the protection of the water supply works at Boonton, has not yet (1927), been placed in service. The tanks are submerged under operation, so that no tough mat of scum will be formed. It is possible, however, to operate them with a lowered water level. Sludge is to be admitted at multiple inlets throughout their length; meanwhile there will be an equivalent displacement of liquid to a so-called regulation tank, held in reserve and having a lowered water level. Sludge is to be withdrawn through a system of steep-sided hopper bottoms. Provisions are made for collecting gas, which will be stored in a small holder near-by, and will be burned in a glass-covered sludge bed, or used to raise the temperature of the tanks, should it later be decided to install a heating system. The tanks are protected by an earth cover.

The tank shown in Fig. 3 is the so-called Dorr digester, of the gas-collector type. Others, built without covers and with simple elevated covers, are essentially similar in that they are plain cylindrical tanks with a flat bottom and provided with the Dorr digester mechanism. The purpose of this contrivance is to break up scum, to produce a mixing and circulation of the sludge, and to push it along the flat bottom to the sludge outlet. The Dorr Company has supplied the equipment for a number of such installations now in operation.

The digestion tanks at Plainfield, N. J. (Fig. 4), are thought to be the first in America to utilize the artificial heating of sludge by hot-water circulation and the patented floating cover. The cover, which is of simple wood

\* Public Works, July, 1925.

construction, rises and falls with the admission or withdrawal of sludge or liquid and permits the collection of gas in the central dome. No trouble has occurred from scum, odors or foaming sludge. Sludge is admitted to the tanks through hose lines inserted in any one of four inlets in the cover, and is withdrawn through a single central pipe. The tanks were built at a very low cost.

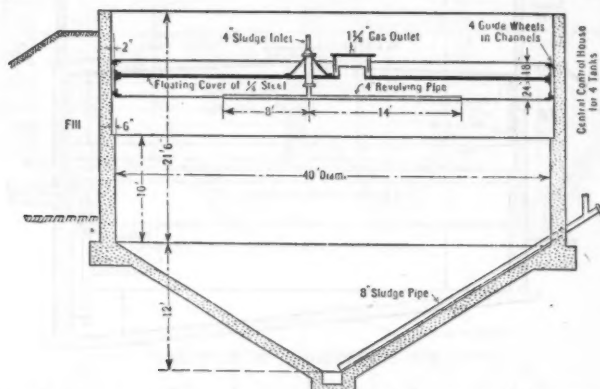

FIG. 6.—SPRINGFIELD, ILL., TANK.

The design for Lynbrook, N. Y., by Mr. Fuertes, is shown in Fig. 5. These tanks were intended both for primary solids and for surplus activated sludge. Provisions are made for heating the sludge, for circulating it, by pumping, for mixing and for reaction control. The unusual cover, of steel and in the form of a gas-holder, is to store the gas produced for utilization about the plant as required.

The design for Springfield, Ill., by the firm of Pearse, Greeley and Hansen (Fig. 6), is another example of an attempt to provide means for controlling digestion and collecting gases. A floating steel cover is proposed, with special means for introducing and distributing the sludge. The elevation of these tanks, as is true of all the examples cited, is not dependent on that of the flow line of the outfall sewer, so that appreciable economies in construction costs are possible by avoiding deep excavations in water-bearing soil.

#### FUTURE DEVELOPMENT

With the development of more accurate knowledge of the nature of anaerobic digestion, this process seems capable of being used with more intelligence than in the past. It furnishes an economical method for the inoffensive disposal of organic wastes and will undoubtedly have broad application. Information developed in the last few years has had a marked effect on the trend of design of sludge digestion tanks. There is, however, much to be learned as to the absolute capacities required under different conditions. To this end engineers should continue the generous publication of accurate operating data.

## DISCUSSION

HARRISON P. EDDY,\* M. Am. Soc. C. E.—The changes which have been taking place in the art of sewage disposal since about 1918, are somewhat radical. For many years, the primary effort was to produce an effluent which would satisfy local conditions, and the problem of sludge disposal, while recognized as being troublesome, was subordinated in a measure. The tendency, to-day, is clearly toward more complicated treatment plants and the division of the processes into a number of stages.

Formerly, little attention was paid to the matter of odors produced at treatment plants. It was common practice to discharge raw sludge into lagoons or on to open drying beds, often resulting in the dissemination of offensive odors. At present, determined effort is made to prevent the escape of odors in so far as possible. Sludge digestion is now (1927), commonly practiced to accomplish this.

It has long been recognized that temperature has a material effect on decomposition, but sufficient attention has not been given to this phase of the digestion process. It is well known that, in the colder climates, streams which are so polluted as to create offensive odors in summer are relatively inoffensive in winter.

It has not always been recognized that the storage of sewage solids on the stream bed in winter is accumulating trouble for the following summer. In the colder climates of this country such solids are subjected to a refrigerating process for perhaps six months of the year. The temperature of the river water is so low that it prevents the solids from changing materially, but when summer comes, with an increase of 65° or more, in water temperature, decomposition of the accumulated solids creates a load on the stream which is greater than the current load.

The digestion of sludge in unheated tanks takes place under similar conditions, but by controlling the temperature, as Mr. Gould has indicated, active digestion can be maintained continuously and it is possible materially to reduce the storage capacity required. Heat may be provided by burning the gas evolved from the digesting sludge; but this introduces additional complications because of variations in the rate of gas production, the need for regulation of pressure, and the necessity for adequate precautions against accidental explosion.

Atmospheric oxygen, mingling with the gas in a tank, may form an explosive mixture. Such mixtures, containing between 5.5 and 12.8% methane, are explosive, and may be produced by many conditions, such as those following the partial removal of sludge from a tank.

There is difference of opinion as to the mechanical equipment which should be provided for separate sludge-digestion tanks. It is practically impossible to introduce the sludge uniformly throughout the tank. This difficulty may be overcome in a measure by artificial mixing. A mechanical stirring device may be placed at the bottom of the tank where solids are supposed to accu-

\* Cons. Engr. (Metcalf & Eddy), Boston, Mass.

mulate, but the solids may accumulate in the upper part of the tank, in which case stirring equipment would be more effective at the top. Experience has also shown that there may be an accumulation of solids in the middle of the tank, with comparatively clear water above and below. These conditions are probably due in large measure to the kind of biological action taking place, although temperature and other physical conditions undoubtedly are important factors.

Some biological processes are carried out most advantageously at certain rather definite points of acidity or alkalinity. It is logical that there should be an optimum reaction for the digestion of sewage sludge. The reaction may be regulated by the addition of chemicals. Having established favorable digestion, it is important to keep a quantity of sludge in the tank sufficient for seeding the freshly deposited sludge.

In developing the art of sewage treatment, in an effort to prevent offensive odors, to secure a high degree of purification, and to handle the sludge under advantageous conditions, engineers are introducing processes and equipment which add operating complications. These also add to the cost of design, construction, and operation.

It is difficult to secure funds for proper operation, but it is more difficult to secure operators who have the technical knowledge and skill required to operate such plants successfully. This country has advanced from the simple, "fool-proof" sewage treatment plant of the Nineties, of which very little was required except good luck, to the highly complicated mechanical plants, like that at Milwaukee, Wis., and like some of the separate sludge digestion plants. The difficulties ahead in the field of operating these plants constitute one of the most serious problems confronting the engineer practicing in this field.

JOHN R. DOWNES,\* Esq. (by letter).—In the writer's opinion, the work of Mr. Gould stands out as of the greatest importance to the art of sewage disposal in that it sums up so accurately the present-day knowledge and information on sludge digestion.

Those who have been intimately connected with scientific investigations have realized for some time the necessity of having the *status quo* of developments presented from the engineering standpoint. Mr. Gould has presented the matter so ably that any analytical discussion would simply tend to befog that which he has made extremely clear.

He suggests that inert material might settle out in digestion tanks to the extent of decreasing the available digestion space. In reply it may be stated that in tanks of the design shown by Mr. Gould, in Fig. 4, which are practically flat-bottom tanks, only from 2 to 4 in. of gritty, inert material has settled out during a period of two years, notwithstanding the fact that a grit chamber installed at the end of the two-year period removed about 6 cu. ft. of grit daily from the incoming sewage. In the settling tanks and flow channels the grit tends to separate from the sewage and from the thin watery green sludge, but, in the digestion tank, it becomes rather intimately incorporated in the more

\* Supervising Engr., The Plainfield and Dunellen, N. J., Sewage Disposal Works, Bound Brook, N. J.

viscous, ripe sludge and is carried out with the latter. This specific information was not available at the time the paper was prepared.

WILLEM RUDOLFS,\* M. Am. Soc. C. E. (by letter).—This admirable paper is one of the best attempts to bring together and apply the findings in this field during the last few years. In this case a discussion from the standpoint of an investigator must confine itself to supporting evidence and possibly to the emphasis of some minor details of practical interest to the designing engineer.

The course of digestion of fresh sewage solids is essentially the same in septic tanks, two-story tanks, and separate sludge digestion tanks. However, the difference in the construction of these tanks indicating their use is of great importance in connection with the digestion capacities and the manner of operation. In septic tanks and two-story or Imhoff tanks, two distinctly separate processes are combined: (1) Sedimentation, which is a purely mechanical process; and (2) digestion, which is a purely biological process. Although there is no relation between the two processes, in a septic tank both must take place within the same tank, and in the case of an Imhoff tank there is a more or less intimate connection between the upper and lower compartments. In an Imhoff tank, sewage solids settle and fall through the slots and are supposed to remain there until they are decomposed. This is only partly true, since the solid particles (except at the bottom of the tank when very old sludge is present) are in constant motion, either up or down, depending on whether or not the particles carry entrained gas. Part of this material as well as a part of the liquefied material is displaced by the incoming fresh material. The displaced materials leave the tank with the effluent. From the standpoint of best possible results the processes of sedimentation and digestion, unlike in principle, cannot be combined because, in order to obtain the best possible sedimentation, the suspended solids and partly liquefied material should be prevented from rising and contaminating the effluent.

With separate sludge digestion tanks the replacement discharge does not take place; or, in other words, practically the whole volume of material added must be withdrawn. Studies on operating tanks that treat fresh solids have shown that only from 4 to 8% of the volume is reduced, due to biological activities and about the same percentage when activated sludge is digested. Obviously, when thin fresh solids are kept in a tank without further concentration the digestion capacity would be much greater than in a two-story tank. Fortunately, fresh solids that are added to a tank separate quickly from the water. This takes place in separate sludge digestion tanks as well as in Imhoff tanks, and thickened sludge in separate sludge tanks can be obtained by decantation, whereas in Imhoff tanks the decantation process takes place automatically, although it cannot be controlled. With control, the operator is able to prevent contamination of the effluent from the settling units and thereby prevent possible nuisances due to odors and difficulties in overloading of sprinkling filters.

Little information is available on the condensation of sludge from domestic sewage. Decantation of the comparatively small quantities of supernatant

\* Chf., Dept. of Sewage Research, State Agri. Experiment Station; Prof. and Head of Depts., Water Supplies and Sewage Disposal, Rutgers Univ., New Brunswick, N. J.

liquid is rather easy, but the question arises at once as to how far such displacement of liquor may be carried. Exhaustive laboratory experiments have shown that sludge concentration can be practiced to a high degree without detrimental effect to digestion activities.

The longer the digestion schedule, the larger is the digestion capacity required. Assuming good operation, the effective digestion capacity of a separate sludge digestion tank can always be the same or less than for an Imhoff tank. As soon as control is practiced the digestion capacity of a separate sludge tank is considerably less. This is especially true in cases in which heat is applied. Heating of a separate sludge tank is a comparatively simple matter, whereas experiments conducted by Dr. Imhoff to heat the digestion compartment of an Imhoff tank failed because the temperature could be raised only from 2 to 3° Fahr. without excessive heat supply. Moreover, too great quantities of hot water introduced would tend to produce a thin sludge.

In the past, the designer did not have available a number of fundamental facts. Several factors influencing digestion, such as seeding, temperature, and reaction, have been investigated and are now largely available to the engineer. A few curves are submitted herewith to emphasize and illustrate the more important single factors.

The most important single factor known to the writer at present is the inoculation or "seeding" of raw sewage sludge with sludge that has undergone decomposition. Such sludge has a well-balanced group of organisms, and their enzymes, responsible for rapid decomposition, contain the necessary chemical constituents to counteract the effects of intermediate decomposition products formed during the early stages of digestion (Fig. 7). Although the total quantity of gas produced per given quantity of organic matter is not influenced by seeding, the material not inoculated requires about six times longer for digestion than the properly inoculated sludge at the same constant temperature of 70° Fahr.

The effect of temperature is second in importance (Fig. 8). Measured by the digestion time required, unseeded fresh solids at 50° Fahr. require six times longer than material digested at 82° Fahr., which is considered the approximate optimum. Only at very much higher temperatures could it be possible to reduce the digestion time further. With properly seeded mixtures the digestion time at 70° Fahr. is nearly five times shorter than at 50° Fahr. Although the information available is comparatively scarce, the average yearly temperature taken at a number of sewage disposal plants varies between 52 and 58° Fahr. It is evident, therefore, that sludge heating is of great importance in a northern climate, although it should not be forgotten that the average yearly temperature of the material in the sludge digestion tanks at Baltimore, Md., is only 52.5° Fahr. This brings up the important question of proper insulation of digestion tanks. If tanks are built above ground there should be at least an earth fill around them, although it might be better if some one would devote time to insulate them properly. Insulation is not only important when tanks are built above ground, but also when tank contents are influenced by ground-water.

The relation between changes in the reaction of the medium and the gross activities of the micro-organisms is shown in Fig. 9. For convenience, the accumulated gas production from a mixture of sewage solids, with the reaction controlled by hydrated lime, is compared with gas production of a mixture digesting under "natural" conditions. It should be kept in mind that this cannot always be done, because under certain circumstances liquefaction might be too great. Although lime retards initial gas production, the amounts produced after 60 days, with the reaction controlled by the addition of lime, is more than two and one-half times the quantity produced from the unlimed material.

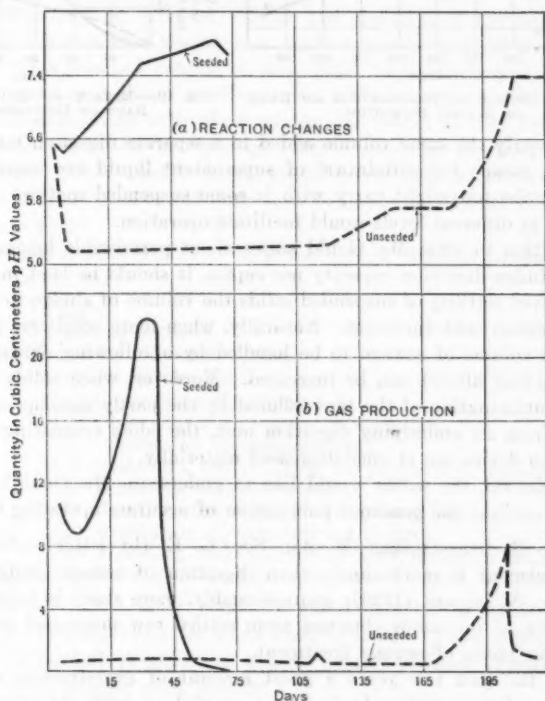

FIG. 7.—EFFECT OF SEEDING ON THE RATE OF SLUDGE DIGESTION.

As pointed out by Mr. Gould the gases produced by decomposition of sewage sludge can be utilized for heating the sludge, blowing air, running pumps, etc. The tendency is to heat the tanks by means of closed circulating hot-water systems with coils running around the tanks. It is obvious that such coils should be continuous. The writer knows of only one case in which the heating coils are placed vertically instead of horizontally, namely, in the new tanks built for the digestion of screenings at Milwaukee, Wis. Offhand it would seem that vertical coils are better from the standpoint of water cir-

culution and possible caking. Experiments made at the New Jersey Sewage Experiment Station have shown that water heated to 140° Fahr. caused no caking.

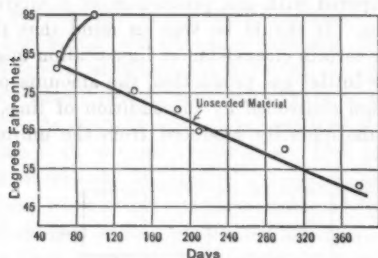

FIG. 8.—EFFECT OF TEMPERATURE ON RATE OF SLUDGE DIGESTION.

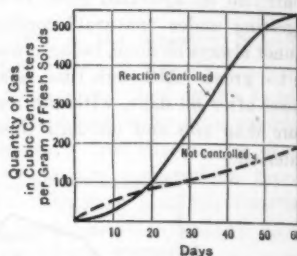

FIG. 9.—EFFECT OF REACTION ON RATE OF DIGESTION.

Since nearly the same volume added to a separate digestion tank must be withdrawn, means for withdrawal of supernatant liquid are important. An overflow at the top might carry with it some suspended matter. Additional "take-offs" at different levels would facilitate operation.

In addition to what Mr. Gould states about permissible loading of tanks based on sludge digestion capacity per capita, it should be kept in mind that with improved settling of suspended solids the volume of sludge to be handled by the digestion tank increases. Naturally, when more solids are retained in a tank the volume of sewage to be handled by a following oxidation device (like sprinkling filters) can be increased. Moreover, when solids are settled without contamination of the tank effluent by the partly decomposed material emerging from an underlying digestion unit, the odors emanating from such an oxidation device are at once decreased materially.

In conclusion, the writer would like to underscore Mr. Gould's plea, that engineers continue the generous publication of accurate operating data.

EDMUND B. BESSELIEVRE,\* M. AM. Soc. C. E. (by letter).—No phase of sewage treatment is more timely than digestion of sewage sludge in separate tanks. At present (1929), unquestionably, more study is being given to the digestion of the solids obtained from settled raw municipal sewage than to any other phase of sewage treatment.

Within the past few years a great amount of experimental work, both laboratory and semi-full scale, has been carried on with the view to determining the important factors in the digestion of sewage solids, for use in designing the necessary structures. This work is of inestimable value; it has enabled engineers to appreciate factors that have been neglected in the past, and to make obsolete plants successful.

On the other hand, abstract theories derived from experimental work, cannot produce results on a large scale, unless all the technical and economic factors are carefully considered before the actual design of the digestion tanks.

\* San. Engr. and Mgr., Eastern Territory, San. Eng. Div., The Dorr Co., Inc., New York, N. Y.

The primary object of digestion tanks is to produce—in a short period of time, without odor, unsightliness, or other nuisance—an inert, inoffensive sludge which may be dried in the open air or otherwise disposed of without offense. This sludge should be of small volume, low in moisture, and free from odor when wet or dry.

In small plants these results should be obtained with the minimum of manual attention and in a minimum area. In large plants, area is perhaps the greatest consideration because adding one or two men may be cheaper than greatly increasing the area.

Observation made in the period since 1925 clearly demonstrates that such results may be obtained. When the digestion of the organic solids is complete, the resultant sludge may represent only 40% of the original dry weight. This lessened volume of wet sludge to be discharged on the drying beds in turn means that a smaller area of beds is required. With the modern plan of covering beds with glass, continuous use of all the drying area may be obtained regardless of weather, further reducing the area required. In small plants, where land is cheap, glass-covered beds at about \$3 per sq. ft. may not be more economical than open beds, but this would seldom hold true in a larger plant.

The main considerations to be given careful thought in designing sludge digestion tanks are:

- 1.—Volume.
- 2.—Shape and number.
- 3.—Simplicity of construction.
- 4.—Operating devices for:
  - (a) Controlling digestion;
  - (b) Observing the progress of digestion;
  - (c) Controlling the temperature;
  - (d) Collecting and utilizing the products of digestion;
  - (e) Removing digested sludge;
  - (f) Handling the overflow of displaced liquor;
  - (g) Admixture of new and old sludges;
  - (h) Handling and overcoming scum troubles; and
  - (i) Moving sludge from one part of a tank to another.

*Volume.*—In the older plants it was impossible to achieve satisfactory results without providing for much sludge storage. This, in general, has been due to the method of operation and not to any unusual characteristic of the sewage or its organic solid content.

As Mr. Gould has shown, the first step in the digestion cycle is an acid fermentation, which is followed to completion later by an alkaline series. Modern research has clearly shown that if a tank is filled with sludge undergoing acid decomposition, the entire tank will be acid. Unless this is overcome artificially, sufficient time must be allowed for the natural reaction to take place. This means large volumes, large tanks, and large area consumption. Dr. Rudolfs and others have shown, however, that if a fresh sludge is added daily to a tank filled with a mass already alkaline, the acidity created by the new raw sludge, will not upset the reaction of the tank, and alkaline digestion will continue. This daily pro-

portion has been roughly placed at from 2 to 3% of the total. Sludge that is not more than 24 hours old, preferably 8 to 16 hours, is defined as fresh, raw sludge. To obtain these results is not difficult and requires little technical skill. In plants that require only the part time of one ordinary laborer per day, successful sludge digestion has been accomplished over periods of years. Naturally warm climates are more favorable to continued digestion, but records show equally satisfactory results in cold northern sections.

Mr. Gould discusses the modern method of expressing the environment for successful digestion—the hydrogen-ion concentration, expressed as pH-values. Apparently, a misunderstanding is current. Several investigators have found that the pH-range for best results varied from 7.2 to 7.6, others from 7.4 to 7.6, or even more. Some operators have taken this to mean that it is necessary to maintain a pH-value of at least 7.2 to 7.4. This is not so. If 7.2 to 7.4 is found to be the best range for some plant, no one should infer or claim that it should be applied arbitrarily to every case. Intensities in pH-values of 7.1 and even in those as low as 6.8 have produced good results. Unless it can be proved that a certain pH-value is necessary to produce good digestion, no extra money should be spent on re-agents to procure a given degree of alkalinity. Only experimental work can determine the most economical limit.

TABLE 2.—RANGE OF pH-VALUES MAINTAINED AT VARIOUS SEPARATE SLUDGE DIGESTION PLANTS.

Location.	pH-VALUE.	
	Liquid.	Sludge.
Hartford, Wis.....	6.8 to 7.0	6.7 to 8.1
Kiel, Wis.....	.....	7.1 to 7.4
Sheboygan, Wis.....	.....	7.4
Antigo, Wis.....	7.2	7.4 to 7.6
Ridgewood, N. J.....	.....	7.0 to 7.4
Storm Lake, Iowa.....	.....	7.2 to 7.6
Sioux Falls, S. Dak.....	.....	7.3

The fluctuation in necessary pH-values in different plants is shown in Table 2. These plants vary in size, characteristics of sludge, locality, operation, etc.

The volume of sludge digestion tanks is a matter of extreme importance. The customary unit of "cubic feet per capita" has led to misunderstanding, because it has not always been clear whether it was based on present, maximum, future, or some intermediate population.

Authorities now agree that a better way is to record the effective capacity on the basis of the solids received in the tank, that is, the cubic content of the digestion tank from the bottom to a point 1 ft. below the over-flow. This point is taken to prevent the discharge of sludge through the over-flow pipe.

As temperature is important for procuring year-round digestion, a digestion tank for a warm climate would require less volume than one for a cold climate. If the warm temperature favors uninterrupted digestion throughout the year, aside from all other considerations, this would warrant the use of a small volume per capita. Conversely, in a colder climate for months digestion is inhibited, and the tank functions as a storage tank only; therefore, sufficient volume must be provided to accommodate the daily sludge contribution for the dead period. No arbitrary scale of the proper volumes per capita can be stated, as other elements besides temperature influence the speed of digestion. The maintenance of a favorable alkaline environment, the characteristics of the sludge itself, and the character of the solids, all tend to influence the digestion time and the volume required. Certain industrial wastes contribute such a large extra load of solids that generate acid products as to require from three to four times as much volume per capita as normal sewage sludge.

Tanks without artificial temperature regulation, and those in which the acid step is not controlled by proper additions of sludge or the use of corrective agents, have a lag in digestion because, during the period of acid fermentation, there is no digestion. This must be provided for in extra volume.

Knowing the optimum temperature and the correct proportioning of raw and digested sludge, an engineer can design tanks that will produce well-digested sludge throughout the year with a minimum of capacity.

Design data of fifty-one plants constructed in all parts of the United States since 1923 show that the average per capita volume in the digestion tanks is 2.87 cu. ft. The range is from 1.15 to 12.0 cu. ft., the latter being for a plant having a large proportion of industrial wastes.

*Shape.*—Assuming that control of temperature and reaction is to be provided, the next consideration is the shape of the tanks.

Construction cost enters into this largely. Simplification by using straight walls, omitting baffles and intricate sections, decreases the initial cost. The simplest form is a vertical cylinder, with no internal walls or baffles and a relatively flat bottom. This simplifies form work and reduces the amount of reinforcing steel, at the same time producing the strongest possible wall. It assures speed of construction and avoids the occurrence of pockets to trap gas.

Practically all the tanks built in the United States and Canada since 1924 have been vertical cylinders. Some have flat bottoms, cleaned mechanically; others have cone bottoms, depending on hydrostatic evacuation of the sludge. Some have flat roofs carried from the tank walls; the writer agrees with Mr. Gould that domed roofs are not only difficult and uneconomical to build, but introduce an element of danger in allowing the accumulation of large volumes of gas which may become extremely explosive if air is admitted to the tank. In modern tanks, with the liquid level maintained at the bottom surface of the tank cover, the only available gas collection space is the small dome, and the danger is negligible.

The number of tanks required is a matter of argument. A study of fifty-one plants constructed since 1923 shows that in all except the largest the number is usually two. As tanks up to 85 ft. in diameter have been in operation for some time, and those of larger diameter may prove equally practical, there is no mechanical reason for providing a large number. Doubtless, economy is best served by fewer and larger tanks. As digestion tanks are provided for the sole purpose of allowing organic solids to undergo a natural process of decomposition, a larger capacity than is required at the start is no detriment. Therefore, fluctuating population is not a good argument for a large number of small tanks.

As no definite advantage has been shown in progressive digestion, that is, transferring sludge from one tank to another, over controlled digestion in one tank, no economic purpose can be served by more than two or three units. Furthermore, in heating one or two large units, the heat loss due to the addition of daily sludge will be less than in smaller units; therefore, it should be possible to maintain more equal temperature. Less heat also will radiate, as the aggregate wall area of the larger units will be less. Furthermore, in places where mechanical units are used for distributing and collecting sludge and releasing gas, a few large units will cost less initially and less to operate than a larger number of small units.

*Operating Devices.*—The next considerations are the means for controlling digestion and temperature, for collecting and utilizing products of digestion, for eliminating scum, for mixing new and old sludge, for removing displaced liquor, etc.

As one of the products of digestion is gas, which when disseminated in quantities in the atmosphere is productive of obnoxious odors, the modern idea, as expressed by Mr. Gould, is to cover the tanks. This is true regardless of locality. Tanks operating, for instance, in the South, would not normally require covers, because there is no need for heating the tanks, and, therefore, for collecting the gas to utilize its heat value; but from the standpoint of control of odor, an uncovered tank is never a certainty, therefore, even in warm climates, covering is frequently advisable, especially where plants are close to residences. The gas may be burned merely to provide against odor, or it may be used as a source of heat or power as required. In any section where a period of cold weather may reduce the tank temperature to the danger point, heated and covered tanks are proper.

Research and observation show definitely that a separate sludge digestion plant with modern digestion units, controlled temperature, and reaction, treating an average municipal sewage will produce sufficient gas to maintain the optimum digestion temperature throughout the year, and, in most cases, will provide heat for the plant buildings and frequently for the glass-covered sludge beds as well. This economy is provided at no cost.

At Antigo, Wis., the cost of electrical current to operate all units of the plant for the eighteen months beginning July 1, 1927, averaged \$30 per month. The total production of gas was 2 300 000 cu. ft. Assuming that this gas had been sold at a rate of 30 cents per 1 000 cu. ft. (a low rate for

a high-grade gas), the total revenue would have been \$690. On this basis the gas produced would have offset the entire cost of electric current for the period. As a matter of fact, the gas was used to heat the digester and the plant buildings; if the required gas had been purchased locally, it would have cost \$215.25 per month. If soft coal had been used, it would have cost more than \$1 000. With an ordinary circular tank, the apparatus is moderate in cost and simple to operate and control.

Mr. Gould refers to the formation of scum in digestion tanks. Even with reaction control scum may form, but, as he states, it is more likely to occur with incorrect reactions. Scum that forms in a tank with gas collection domes in the cover prevents the free and even discharge of the gas and may interfere with the uniformity of flow to the heating system, requiring a holder of considerable volume to equalize the flow. A tank equipped with a revolving mechanism to break down the scum continually will provide an even flow of gas and obviate the gas-holder, except in very large plants where it is desired to store the surplus gas during periods of warm weather. A mechanism of this type is shown in Fig. 3.

A digestion tank, particularly a closed one, should be kept full of sludge and liquid at all times. Withdrawal of sludge to the drying beds will cause the level of the liquid in the tank to lower unless the period of withdrawal is timed to correspond with the period of sludge addition, and this is a simple accomplishment. If the over-flow pipe is trapped and baffled properly, there will be no chance for air to enter the tank during withdrawal periods, and little if any chance for solids to pass out of the tank.

The liquid displaced from the digestion tank is naturally equal in volume to the amount of sludge put in the tank, except during the period when sludge is being withdrawn and admitted at the same time. A large number of plants return this displaced liquid to the inlet side of the sedimentation units. Most of the settleable solids that might pass out of the digestion tank with this liquid are re-settled and returned to the digester, and the volume of this liquid displaced in any one day, as compared to the total volume of sewage flowing through the sedimentation unit during the same day, is so small that, in general, this return of displaced liquid would not upset the operation of the sedimentation tank. However, several State Departments of Health have issued rules requiring the treatment of this displaced liquid separately. This usually entails only the construction of a small sand filter.

Digestion tanks may be heated in several ways. The simplest and cheapest method is to circulate the gas-heated water through the tank by a coil of pipe on the walls. The first form used was similar to the familiar factory heating coil with several pipes running to manifolds at each end. This was found to give a little difficulty in heat loss and ineffective heating of all parts of the coil, so that the favored type is a spiral running completely around the inside face, starting about 2 ft. from the bottom of the tank and having four to six complete turns. As the hot water must go in one end and out of the other, there can be no tendency to clogging or sluggishness of flow.

Observations have shown that the initial temperature of the hot water should be sufficient to transfer approximately 20° Fahr. to the sludge to maintain the optimum range of 75 to 80° Fahr. There is, however, a danger point to be avoided here. If the initial temperature is too high, the sludge may dry and cake too rapidly around the sludge pipes. This will make them ineffective as heating units, and cause a continuing increase in the initial temperature of the water. By experience even in the extreme northern section of the country (Antigo, Wis.), an initial temperature of 120° Fahr. will allow continued satisfactory operation and no caking will result.

Other means of applying heat to the sludge have been suggested, such as circulating hot water through it, depending on the convection currents to warm the entire mass. The writer believes that this method will entail greater heat losses than the pipe-coil method, as the hot water will naturally rise to the surface and pass from the tank with the over-flow; and that in passing upward it will not diffuse through the entire mass, but will flow upward in streams through the sludge, heating only the portion directly adjacent to it in its travel.

When the sludge is completely digested, it should be removed to the drying beds, thus freeing space for new sludge. If hydrostatic evacuation is relied upon solely to move the sludge, this evacuation will not be complete and certain volumes will remain upon the walls and bottoms, caking and eventually reducing the effective digestion space. True, this may be prevented by sprays of water or air operated at the time sludge is withdrawn, or by hand-squeegeeing the slopes; but there will be no guaranty of complete evacuation. The addition of water increases the moisture of the sludge, the driving period, and the volume of over-flow from the top of the tank. Air is apt to cause flotation of solids, forming surface scum. Hand-squeegeeing introduces an element of cost and is not entirely satisfactory. Any of these three methods requires eventual dewatering of the tank and careful cleaning of the surfaces. By means of a mechanism (see Fig. 3), complete evacuation of the sludge may be obtained.

If the sludge is allowed to compact in the bottom of the tank, without any attempt at stirring to procure an admixture between the old, partly digested sludge and the new raw sludge, digestion will be stratified. By providing a means for gently stirring the mass, keeping it porous, and allowing the continuous upflow of the gas in small bubbles, the formation of thick surface scums, which is so common in many tanks, is prevented.

One of the recognized features of modern plant operation is the control of alkalinity in the digestion tanks. This usually consists of adding sufficient lime to the sludge to overcome the acidity. It is simpler to add the small quantity of lime required directly to the daily volume of sludge than to the entire tank volume. Hence, the tank which permits this will be an economical unit in operation. In several cases in the writer's experience with plants of this type, when no attempt at reaction control was made at the start, it has been found that after a period the entire tank contents were acid. It was then necessary to add sufficient lime to the tank to bring the entire mass to the alkaline sludge and after that to add sufficient

lime each day to the new sludge admitted to maintain this alkalinity until tests showed that the tank was entirely in alkaline balance and the daily addition of new sludge would not upset it. This was a very simple operation with the mechanical type of digester. The lime for correcting the tank mass was simply dumped in at the top of the tank and the mechanism worked it down into the sludge; the lime required for the correction of the daily volume was added in the open flume where the sludge was received from the pump at the top of the tank. In one case (Lakeland, Fla.), this entire process occupied a period of about six weeks, and since then the tank has operated most satisfactorily, without odors and without the addition of any lime for more than two years.

Distribution of sludge to all parts of the area of the tank is important to procure the prompt seeding of the raw sludge and to insure complete digestion. The mechanical type of digester provides this, as the revolving mechanism tends to distribute the sludge thoroughly to all points in the tank.

In the writer's opinion, the entire question of design is most important, and engineers in general cannot give too much time to the consideration of every factor in the endeavor to produce plants which will function in a satisfactory manner. The trend of thought as regards sewage treatment works is rapidly changing for the better, and municipalities now are looking upon them as important utilities and are willing to spend the sums necessary for proper construction. The modern sewage treatment plant using the proved means for digesting sludge may be constructed with safety, in sections close to residential districts or near main highways without being considered eyesores or sources of nuisance.

JERRY DONOHUE,\* M. A. M. Soc. C. E. (by letter).—The advance in the art of sewage disposal actuated by a public demand for better treatment plants has been most pronounced in the period since 1900 and indications point to still further perfection in the science in the future. Problems of sewage disposal are now public questions which demand study and analysis not only by municipal officials but by the taxpayers who are called upon to pay the bill and who are demanding better treatment plants. They insist that industries stop the pollution of streams by constructing sewage plants or by combining forces with the municipalities in the study of the problem.

As has been so clearly emphasized by the author, separate digestion and the design of better digestion tanks have been brought about by scientific research, and the development of this method is merely a link in the chain of progress made possible by a working knowledge of the plants which have demonstrated these improvements in successful operation. Some of the advantages of separate sludge digestion may be classified as follows.

*First.—Simplicity of Construction.*—A separate sludge digestion plant is built of simple concrete structures. The digestion tanks are constructed above the water-table, and do not entail any unusual construction cost or expensive excavation.

\* Chairman, Wisconsin Highway Comm.; Pres., Jerry Donohue Eng. Co., Sheboygan, Wis.

*Second.*—This type of plant is operated mechanically. This is a decided advantage to the smaller communities, because it compels careful operation. The old type of sewage disposal plant, when once installed, was neglected and ignored as the municipal authorities paid little attention to operation. The mechanically operated plant requires attention; therefore, the process of sewage purification will go on more efficiently, and better results will be obtained.

*Third.*—*Flexibility as to Expansion.*—Either the sedimentation unit or the digestion unit may be enlarged and thus maintain a balance between them. If conditions should arise which would require an expansion of the digestion compartment, this can be accomplished by merely adding another digestion tank.

*Fourth.*—The separate sludge-digestion type of plant is better adapted to the collection of gases than most other types, as the gases can be trapped in the digestion tank and conducted to a gas burner, thus utilizing a waste product for heat and power and increasing the efficiency of the plant.

*Fifth.*—The period of digestion made possible by the application of heat to the sludge may be extended to a full twelve months, whereas in most types of plants the digestion process stops just as soon as the temperature drops below 50° Fahr. By adding heat to the sludge, the period of digestion can be extended and accelerated, resulting in a saving in capacity. In the middle western and northern climates where the temperature ranges from 30° below zero to 90° or 100° Fahr., above zero, the extension of the period is a decided factor in an economical selection of the type of plant best adapted to the conditions.

The cost of mechanical operation in separate sludge digestion plants is very small. The Hartford, Wis., plant was the first of this kind in the State of Wisconsin. The cost of power to operate this plant is \$15 per month, or about 50 cents per day. This includes all power necessary for motor operation, pumping of sludge, and the lighting necessary in the building.

The total annual cost of operation of the plant at Antigo, Wis., including power, light, chemicals, etc., is 64½ cents per capita. From this cost, however, should be deducted the value of the reclaimed gas, which is utilized in heating the sludge in the digester. If the value of this gas is credited at the rate charged by the local utility company, it would reduce the cost of operation to about 18 cents per capita.

Separate sludge digestion tanks should be built with tight covers to prevent odors from escaping into the air and to permit the efficient collection of gases. The type of cover usually recommended is a concrete slab constructed so as to permit it to expand and contract with the temperature. This concrete slab, which is supported by the circular side walls and through the center by the same truss that carries the operating mechanism that agitates the sludge, rests upon a mastic joint extending the full thickness of the supporting wall. In the center of the supporting wall, the joint is keyed into the concrete. The depth of the key provides space for a crimped copper strip which extends around the full circumference. The joint is filled completely with asphalt which allows

the copper strip to elongate under the stress of the moving concrete top, the copper being firmly held at both ends by its embedment in the concrete roof slab on the top and the concrete wall on the bottom. This form of joint makes the digester both water-tight and gas-tight.

When sludge is withdrawn from the digestion tank, the level of the liquid in this tank is lowered. This raises the question as to the advisability of having a gas container in series with the gas line so that after sludge is withdrawn, gas will follow back into the digestion tank to take the place of the liquid that has been removed. A gas container, with a capacity of one day's or two day's supply, would have the further advantage of stabilizing the flow of gas to the burners and of supplying gas during the time that sludge is being withdrawn, or while repairs are being made to the gas dome or digester.

It is predicted that the development of the next few years will include a combined type of plant of activated sludge with separate sludge digestion, using the better features of each type. This combination will enable smaller cities to consider activated sludge treatment, with the reduction of the sludge by separate digestion. This will largely solve the sludge problem for communities that experience difficulty in disposing of their sludge, for by digestion the volume is reduced 40%, and the residual sludge dries readily and makes a good fertilizer.

The Antigo plant seems to be producing approximately 1 cu. ft. of gas per capita per day. Assuming a conservative estimate of 0.8 cu. ft. per capita per day, the annual value of the gas based on the local utility rate would be about 45 cents per capita. The heating value of the gas, as determined by analysis, averaged 550 B. t. u. per cu. ft., so that a recovery of more than 400 B. t. u. per capita per day can be depended upon. This, reduced to coal at 12 000 B. t. u. per lb., is equal to 6 tons per year per 1 000 population.

KENNETH ALLEN,\* M. A. M. Soc. C. E. (by letter).—In 1897, the Englishman, W. D. Scott-Moncrieff, carried out a most interesting experiment† in passing septic tank effluent through a series of nine trays placed one above another, each containing 6 in. of coke. No deposit had accumulated in 3 months of operation while, in the 8 or 10 min. required for passage through the series, a high degree of purification had taken place. This was attributed in part to the large proportion of liquefying bacteria in the septic sewage which converted much of the organic solids to a condition easily attacked by nitrifying bacteria. The development of these bacteria, in turn, was promoted by the oxygen absorbed by the sewage in dropping from one tray to the next; but the rapidity of purification was also attributed to the selective development, in each tray, of the particular bacteria specially adapted to their environment. Consequently, their activities were carried on under the most favorable conditions, just as division of labor in a well-organized industrial plant brings about the highest productive efficiency. Basing conclusions on "oxygen consumed" tests, Dr. Samuel Rideal found an average of 93%, and on the oxidation of nitrogen, he found that 91.6% purification was brought

\* San. Engr., Sanitation Comm., New York, N. Y.

† Described in the 17th Annual Report of the Provincial Board of Health, Ontario, and in *Engineering Record*, Vol. XXXVIII, p. 561.

about thus in approximately 8 min. In commenting on these findings he stated that\* "the nitrate has developed with extraordinary rapidity and to an extent that exceeds any other process."

The advantages of segregating the several steps of sewage treatment have been recently brought forward by Wynkoop Kiersted, M. Am. Soc. C. E.,† in a plea for so complete a separation of suspended solids by preliminary treatment that oxidation may be rendered easier and more rapid and secondary sedimentation avoided altogether. This is advocated as an ideal for which to strive.

In the activated sludge process, Martin points out the irrationality of utilizing compressed air simultaneously for agitation and aeration. The supply of air required for agitation and that for the supply of oxygen to the sewage are unrelated; and in the attempt to secure adequate treatment an excess for either one or the other of these purposes will ordinarily be used. Martin states,‡ "this difficulty would be avoided if the stirring and the aeration were effected independently." In connection with septic and Imhoff tanks, Dr. Rudolfs has stated that§ sedimentation and digestion, inasmuch as they are two distinctly separate processes, cannot be combined for the best possible results because they are unlike in principle. Mr. H. C. H. Shenton has expressed the same opinion.||

These examples illustrate the trend toward a separation of the functions involved in sewage treatment in general, in order that each may be carried out under the most favorable conditions.

In sludge digestion as ordinarily practiced, there is a tank influent of fresh sludge with, perhaps, a percentage of ripe sludge for seeding. After entering the tank, which is usually built as a vertical cylinder, this material is intimately mixed with the other contents by circulation or by mechanical stirring. It has been found that this mixing process promotes bacterial activity with the formation and release of gas and, at the same time, retards the formation of scum. To make room for the inflowing sludge an equal volume of the contents of the tank is drawn off as supernatant or as digested sludge.

If the process is properly controlled for a sufficient period, the sludge thus withdrawn is dark in color, drainable, and inodorous; but as it comprises a part of the sludge that has entered the tank each day for, say, 40 days, representing the length of storage, it is evident that it cannot all be completely digested. The question arises as to whether or not a gradual progression of the sludge in a long horizontal tank of relatively small cross-section—provided with stirring apparatus to ensure a thorough mixing in that particular cross-section at a number of points—would not produce an equal result in less time or a more thoroughly digested product in the same time. It is probable that, with the varying condition of the sludge during the period between its entrance and discharge from the tank, there would be a corresponding varia-

|| "Common Defects at English Sewage Disposal Works."

tion in the specific type of bacteria, requiring different pH control and temperature for optimum results. In a tank of this kind it would seem fairly reasonable to approximate these requirements at perhaps three or four points.

With the exception of control, the Merchantville-Pensauken tank, converted about 1924 from a septic tank to a digestion tank, complies in principle with the writer's suggestion.\* As reconstructed, this tank is in the form of a baffled channel 6 ft. wide, 10 ft. deep, and 240 ft. long, giving a capacity of about 2 cu. ft. per capita for 11 000 persons. The sludge flows very slowly through this channel until it is drawn at the farther end, some time previous to which it has become black and thoroughly digested. The sewage flow averages about 1 000 000 gal. per day. In March, 1927, samples drawn at ten different points between the inlet and outlet ends showed that† "all samples after Station 5 were well digested." In a test made in February, 1927, the pH rose from 6.0 in the influent to 7.4 at Station 6 and 7.6 at the effluent. Between the sixth and eighth stations, gas evolution was very vigorous and the final product, after 9 months' retention, was black, granular, tarry in odor, and had a 75% reduction of biological oxygen demand. In a week or ten days of warm dry weather it will shrink from a depth of 13 in. to 4 in. on the drying beds and then can be heaped up and burned to a fine ash without additional fuel. According to Maj. M. J. Blew, Research Engineer, North East Sewage Treatment Plant, Philadelphia, Pa., the time of retention can be reduced about 20% by returning the tank supernatant back to the influent of the sedimentation tank, and it can be further reduced to 4 or 5 months by seeding with digested sludge, while by temperature control it can probably be cut to 6 weeks, or 2 months. The satisfactory results secured without pH control or artificial heating would undoubtedly be exceeded considerably with the adoption of such measures. In applying the principle of progressive digestion, two general types of construction are possible. By the first, the tank would consist of a long conduit slightly below the hydraulic grade, but with a gentle upward gradient to enable the released gases to collect in a dome at the outlet end. Baffles at the inlet would distribute the incoming sludge, seeded and limed, if necessary, and provision for pH control and for the removal of deposits, if formed on the rounded invert, by flushing or mechanical means, would be made at several points between the two ends of the tank.

By the second arrangement digestion would take place by steps in several separate tanks operated in series, each under independent control, the units of which could be of the "Boonton" type, as shown in Fig. 2, or of the usual Dorr type.

A preliminary digestion in Imhoff tanks followed by completion of the process in a relatively small separate tank, as advocated for large plants by Karl Imhoff,‡ M. Am. Soc. C. E., is in accordance with this idea. The sludge

\* *Public Works*, June, 1924, p. 184, July, 1924, p. 213, November, 1927, p. 409, and December, 1927, p. 468.

† *Loc. cit.*, December, 1927, "Merchantville-Pensauken Sewage Treatment Plant," p. 470.

‡ "The Arithmetic of Sewage Treatment Works," by Karl Imhoff and Gordon M. Fair, p. 37.

chamber in the Imhoff tank would be of smaller size and the partly digested contents pumped in a condensed form to the separate tank. Acid fermentation is avoided and optimum temperatures can be provided, all with minimum sludge capacities.

Prüss has elaborated the same idea.\* He computes the profit (after paying capital and operating charges) in liters of sludge gas per day per capita when selling at 6 pfennigs per cu. m. With single-stage digestion at either 12° or 25° cent., the surplus or profit is 0.2 liters, and 3.0 liters with two-stage digestion when heating the second unit, only, to 25° cent.; that is, if the surplus gas were sold—as is customary in Germany—the net profit with two-stage digestion would be fifteen times that with a single tank.

Whether the cost of providing more than two stages to the process would be justified is not known, but if there is an economic advantage in adding an auxiliary tank to the sludge chamber of an Imhoff tank there would appear to be a still greater economy in providing optimum conditions for all stages in a single tank near the ground surface.

RICHARD H. GOULD,† M. AM. SOC. C. E. (by letter).—Discussions often-times contribute material and thoughts more valuable than the original paper. From the writer's standpoint, the discussions submitted in this case certainly are most interesting and instructive.
